Utilitat dels models matemàtics amb neuroimatge pel diagnòstic i l'estudi de la variabilitat en la malaltia d'Alzheimer i la demència frontotemporal

Tesi presentada per:

Agnès Pérez Millan

Per optar al grau de doctora per la Universitat de Barcelona

Programa de Biomedicina

Facultat de Medicina i Ciències de la Salut

Dirigida per:

Roser Sala Llonch i Raquel Sánchez del Valle Díaz

Barcelona, 2023

A la meva àvia Concepció

Barcelona, 16 d'octubre de 2023

La Dr. Roser Sala Llonch, doctora en Medicina per la Universitat de Barcelona i la Dra. Raquel Sánchez del Valle Díaz, doctora en Medicina per la Universitat de Barcelona,

CERTIFIQUEN

Que la memòria titulada *"Utilitat dels models matemàtics amb neuroimatge pel diagnòstic i l'estudi de la variabilitat en la malaltia d'Alzheimer i la demència frontotemporal",* presentada per Agnès Pérez Millan, ha estat realitzada sota la nostra direcció i considerem que reuneix les condicions necessàries per ser defensada davant el Tribunal corresponent per optar al Grau de Doctor.

Signat,

Dra. Roser Sala Llonch

Unitat de Biofísica i Bioenginyeria,

Departament de Biomedicina,

Universitat de Barcelona

Dra. Raquel Sánchez-Valle

Unitat d'Alzheimer i altres trastorns cognitius,

Servei de Neurologia

Hospital Clínic de Barcelona

AGRAÏMENTS

Un cop arriba el moment d'escriure els agraïments és quan t'adones que una etapa més s'ha acabat, una etapa que es podria descriure com una muntanya russa molt enriquidora, però a la vegada molt dura. Voldria començar agraint a totes les persones que han col·laborat en aquesta tesi o han fet possible que jo em decidís per fer-la, des dels meus mestres de l'escola fins a les meves directores de tesi passant per la meva família i amics, perquè sense tots ells no hauria estat possible. El procés de la tesi en si ha estat realitzada gràcies a l'ajuda i el suport de moltes persones, però en especial voldria transmetre el meu agraïment:

M'agradaria començar per les meves directores de tesi, la Roser i la Raquel, ja que són les persones que han lluitat tant com jo perquè tires endavant aquesta tesi. Gràcies per l'ajuda, la guia, l'esforç, les hores de discussió, els consells i pels coneixements que m'emporto tant científicament com en l'àmbit personal. Gràcies per la confiança dipositada en mi, gràcies per la llibertat donada durant aquests anys i gràcies per enriquir-me com a persona. Resumint, aquesta tesi no hauria estat possible sense cap de les dues.

Bea, Jordi i José sense vosaltres la tesi no hauria estat possible, la vostra ajuda i disposició ha estat sempre present. M'hauria estat impossible recopilar tantes imatges, comprovar diagnòstics i consultar dubtes a mi sola. En especial a la Bea, gràcies per deixar-me robar el teu ordinador per descarregar imatges per ser el

més ràpid i per les estones asseguda al meu costat mirant que tots els pacients tinguessin diagnòstic i el nombre de visites correcte. Parlant d'imatges, no em puc oblidar de la meva directora de tesi, la Roser que em va animar i ajudar a fer un doctorat sobre imatges de ressonància magnètica.

Gràcies a tots els membres de la Unitat d'Alzheimer i altres trastorns cognitius (alguns ja mencionats), inclosa la meva altra directora, que almenys si s'han escandalitzat en alguna pregunta molt bàsica meva, han dissimulat i han respost molt amablement i han tingut una paciència de sant explicant conceptes molt bàsics a una física que no tenia ni idea. Raquel gracias por hacerme entender que por muy maravilloso que parezca numéricamente, no necesariamente tiene que tener sentido clínico. Albert, gràcies per tots els comentaris i discussions que hem tingut al llarg de la tesi i que l'han enriquida. Sergi, gràcies per explicar-me més d'una vegada i dues, els diagnòstics de la DFT. Neus i Núria, gràcies per estar disponibles sempre per poder resoldre dubtes i donar suport en tot. Diana i Jordi, gràcies pel companyarisme i per ser del grup menú infantil. Adrià gràcies pels consells, i explicar-me una mica més sobre les proves neuropsicològiques. Anna gràcies pels conceptes bàsics de genètica que he pogut aprendre al teu costat. Mircea, Guada, Andrea, Yolanda, Marta, Lorena, i a tots gràcies per col·laborar en la tesi, el suport, els dinars i els sopars de joves.

A l'anomenat team "celulitas" (i algun infiltrat) que no compartim recerca, però sí espai. Natalia, Paula, Marta, Berni, Ale, Ignasi, Hector, Marc, Mar, Patri, Viki, Africa, Alicia, Rafa, Esther que us haig de dir. Gràcies per fer aquesta tesi suportable, gràcies pels esmorzar de xafardejos i pels dinars de més xafardeig,

pels consells, pels plans i sobretot per ser la via d'escapament quan no em surt res del codi. Acabem la tesi i no heu aconseguit que agafi una pipeta, ara bé heu aconseguit que entri el lab sense por i que entengui alguna cosa del que feu amb les vostres cèl·lules. També gràcies pels consells de com gestionar el doctorat. Carol no ets del team "celulitas" perquè ets team peixera, per estar d'infiltrada, gràcies pels consells i per les converses de divendres tarda quan estem soles.

Many happy memories and people come to my mind when I remember the time spent in Paris. Bertrand, thanks for welcoming me to the group, for your time, and your guidance. Thanks for making everything very easy. Finally, thanks for all the knowledge I learned and brought home.

Mar i Elba, crec que sou les dues persones juntament amb la mama que heu patit molt amb aquesta tesi. Crec que heu estat un pilar per acabar-la i per superar aquest últim any de tesi. Us podria dir moltes coses, però ja estan dites i les sabeu perfectament. Simplement continueu estant presents per molt de temps!

Als meus amics, en especial el Bang Club: Laura's, Pol's, Sílvia, Francesc, Miguel, Ferran i Jöan gràcies per l'amistat i el suport per aconseguir acabar la carrera i continuar amb la tesi. Gràcies per estar sempre presents. Mariona's, Uma, Quim, Víctor's, Marc, Pau, Pol, Nil, Natàlia, gràcies per tots els moments de desconnexió tan necessaris.

Finalment, a la meva família gràcies per ser-hi sempre donant suport i estima de forma incondicional. Per fer companyia fins altes hores de la nit, per animar-me i no deixar-me caure, però sobretot per l'educació i els valors en la perseverança,

la lluita, la constància, i el tracte a les persones que m'heu ensenyat des de ben petita. Tot i que hi ha hagut moments de lluita constant.

No puc acabar sense donar cert reconeixement a la xocolata que ha fet una gran contribució en aquesta tesi sobretot en l'escriptura, sense ella no hauria acabat aquest document.

PRÒLEG

Aquesta tesi, presentada per a l'obtenció del títol de Doctor per la Universitat de Barcelona, és el resultat de diferents estudis. Aquesta tesi segueix el format del compendi de publicacions, i inclou quatre articles publicats o acceptats revisats per parells, en els quals la candidata era primera autora o primera autora amb la mateixa contribució (indicat amb *), i dos manuscrits enviats per a la seva publicació com a primera autora. Els sis treballs es presenten en el següent ordre:

1. **Agnès Pérez-Millan,** José Contador, Raúl Tudela, Aida Niñerola-Baizán, Xavier Setoain, Albert Lladó, Raquel Sánchez-Valle, Roser Sala-Llonch. Evaluating the performance of Bayesian and frequentist approaches for longitudinal modeling: application to Alzheimer's disease. Scientific Reports 2022; 2022 Agost 24. DOI:10.1038/s41598-022-18129-4. IF (2022): 4,6; Q2 Multidisciplinary Sciences.
2. **Agnès Pérez-Millan,** Sergi Borrego-Écija, Neus Falgàs, Jordi Juncà-Parella, Beatriz Bosch, Adrià Tort-Merino, Anna Antonell, Nuria Bargalló, Lorena Rami, Mircea Balasa, Albert Lladó, Roser Sala-Llonch, Raquel Sánchez-Valle. Cortical thickness modeling and variability in Alzheimer's disease and frontotemporal dementia. Acceptat en Journal of Neurology. IF (2022): 6,0; Q1 Clinical Neurology.
3. **Agnès Pérez-Millan,** José Contador, Jordi Juncà-Parella, Beatriz Bosch, Laia Borrell, Adrià Tort-Merino, Neus Falgàs, Sergi Borrego-Écija,

Nuria Bargalló, Lorena Rami, Mircea Balasa, Albert Lladó, Raquel Sánchez-Valle, Roser Sala-Llonch. Classifying Alzheimer's disease and frontotemporal dementia using machine learning with cross-sectional and longitudinal magnetic resonance imaging data. Human Brain Mapping 2023; 2023 Gener 20. DOI: 10.1002/hbm.26205. IF (2022): 4,8; Q1 Neuroimaging.

4. **Agnès Pérez-Millan,** Bertrand Thirion, Neus Falgàs, Sergi Borrego-Écija, Beatriz Bosch, Jordi Juncà-Parella, Adrià Tort-Merino, Jordi Sarto, Josep Maria Augé, Anna Antonell, Nuria Bargalló, Mircea Balasa, Albert Lladó, Raquel Sánchez-Valle, Roser Sala-Llonch. Beyond group classification: probabilistic differential diagnosis of frontotemporal dementia and Alzheimer's disease with MRI and CSF biomarkers. En revisió.
5. **Agnès Pérez-Millan,** Uma Maria Lal-Trehan Estrada, Neus Falgàs, Núria Guillén, Sergi Borrego-Écija, Beatriz Bosch, Jordi Juncà-Parella, Adrià Tort-Merino, Jordi Sarto, Josep Maria Augé, Anna Antonell, Nuria Bargalló, Raquel Ruiz-García, Laura Naranjo, Mircea Balasa, Albert Lladó, Roser Sala-Llonch, Raquel Sánchez-Valle. The Cortical Asymmetry Index (CAI) for subtyping dementia patients. En revisió.
6. **Agnès Pérez-Millan***, Sergi Borrego-Écija*, John C. van Swieten, Lize Jiskoot, Fermin Moreno, Robert Laforce, Caroline Graff, Mario Masellis, Maria Carmela Tartaglia, James B. Rowe, Barbara Borroni, Elizabeth Finger, Matthis Synofzik, Daniela Galimberti, Rik Vandenberghe, Alexandre de Mendonça, Chris R. Butler, Alexander Gerhard, Simon Ducharme, Isabelle Le Ber, Isabel Santana, Florence Pasquier, Johannes

14-3-3	Proteïna 14-3-3

CAPÍTOL 1

Introducció

1.1 IMPACTE GLOBAL DE LES DEMÈNCIES

El deteriorament cognitiu i la demència són un problema de salut freqüent poblacionalment i generen un alt grau de discapacitat i mortalitat. Actualment, en tot el món hi ha aproximadament 50 milions de persones diagnosticades amb demència i s'espera que aquesta xifra augmenti fins als 131 milions el 2050. El cost de les demències pels sistemes de salut és elevat, en 2015 eren 818 bilions de dòlars a escala mundial, i cada cop ho serà més, s'esperà que en 2050 sigui 1 bilió de dòlars (1).

Clínicament, les demències es caracteritzen per un deteriorament cognitiu i conductual prou greu per afectar l'activitat habitual de les persones que la pateixen. La demència no forma part de l'envelliment normal de les persones, però l'edat és el factor de risc més important per patir una demència, aquest fet fa que la demència sigui un repte global del nostre segle. A mes de l'edat, ser del sexe femení és també un factor no modificable de risc per patir una demència. Les demències neurodegeneratives es consideren malalties altament heretables. Tot i això, només una minoria dels casos es poden considerar que presenten una causa genètica. En aquests casos, la presència d'una mutació és un factor determinant i la malaltia s'hereta amb un patró de transmissió autosòmic dominant.

La paraula demència, no defineix una única malaltia, és una síndrome que engloba diverses malalties, tot i que els símptomes i les comorbiditats se superposen amb freqüència (2). Les malalties neurodegeneratives més comunes que causen demència són la malaltia d'Alzheimer (MA), la demència amb cossos de Lewy, i la demència frontotemporal (DFT) entre d'altres. En molts casos, les característiques clíniques d'aquestes malalties se superposen dificultant el seu diagnòstic, podent conduir a un diagnòstic erroni (3–5). En aquest sentit, es necessiten biomarcadors diagnòstics, és a dir, característiques bioquímiques, de neuroimatge o d'un altre tipus que siguin mesurables i capaces d'identificar el procés patològic.

Biològicament, les demències neurodegeneratives es desenvolupen lentament durant molts anys abans que siguin diagnosticades i fins i tot abans que apareguin

els primers símptomes (6), durant el que s'anomena la fase preclínica. Poder detectar que les desencadena ens pot ajudar a desenvolupar intervencions per prevenir-les o endarrerir l'aparició dels símptomes. Durant molts anys es va considerar que la demència no era tractable ni prevenible, però un cop s'ha deixat enrere aquesta creença, s'estan posant molts esforços per trobar tractaments efectius (1). Per aquest motiu, és cada vegada més necessari, identificar biomarcadors que siguin capaços de traçar la seva evolució i la resposta als fàrmacs.

1.2 MALALTIA D'ALZHEIMER

La MA és la demència més freqüent, englobant el 60-70% dels casos de demència al món (6,7). Es tracta d'una malaltia molt llarga, on els canvis histopatològics comencen dècades abans de l'aparició dels primers símptomes (8). La MA es caracteritza clínicament per un deteriorament cognitiu progressiu, on la pèrdua de la memòria és un dels trets principals, però també afecta el llenguatge, les funcions executives i les capacitats visuoespacials (9,10). Aquestes alteracions cognitives s'acompanyen de trastorns conductuals com l'apatia o la irritabilitat entre d'altres. Les alteracions cognitives i conductuals condueixin a una pèrdua de funcionalitat i autonomia progressives i irreversibles actualment.

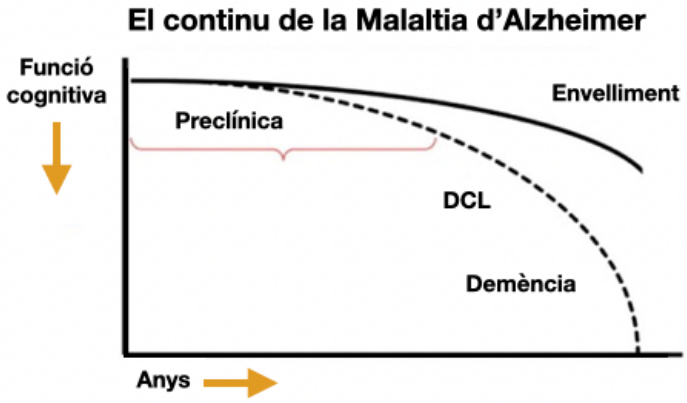

Figura 1: Mostra les fases clíniques que presenta la malaltia d'Alzheimer, s'observa una primera fase preclínica, procedida per una fase amb deteriorament cognitiu lleu (DCL) i finalment la demència. Figura adaptada de (11).

El nom de MA honora el nom del Dr. Alois Alzheimer que en 1906 va descriure el cas, d'Auguste D, una dona de 51 anys, que presentava pèrdua de memòria progressiva, desorientació i al·lucinacions, que la portarà a morir amb 55 anys (12). En aquell moment va ser descrita com una malaltia específica de l'escorça cerebral, ja que era més prima del normal (presentava el que es coneix avui en dia com atròfia). També mostrava una pèrdua neuronal i uns cúmuls anòmals intraneuronals que es van nomenar cabdells neurofibril·lars. Actualment, la MA es defineix pels dipòsits de plaques extracel·lulars d'amiloide i dipòsits intracel·lulars de la proteïna tau hiperfosforilada. L'anomenada "hipòtesi amiloide", encara que discutida per alguns autors, és la teoria més acceptada per explicar el procés fisiopatològic de la malaltia. Aquesta teoria posa com fet clau la diferència entre les formes amiloidogèniques i no amiloidogèniques de la proteïna amiloide que desencadenaria una sèrie de processos que conduirien a la disfunció sinàptica i mort neuronal, entre altres efectes. Seria aquesta disfunció

sinàptica i especialment la mort neuronal la que acabarà provocant el deteriorament cognitiu i conductual característic de les persones que pateixen MA.

Els dipòsits de proteïna amiloide i tau hiperfosforilada podrien començar més de 20 anys abans dels primers símptomes, aquesta etapa de la malaltia es coneix com a fase asimptomàtica o preclínica de la malaltia. L'inici dels símptomes, o fase prodròmica de la malaltia es correspon amb un deteriorament cognitiu lleu (DCL), que evolucionarà amb el pas dels anys, a la fase de demència de la malaltia, com es pot observar en la Figura 1 (11,13).

La majoria dels casos de MA tenen una etiologia multifactorial, i no són determinats per alteracions genètiques concretes, i es consideren formes esporàdiques. Tanmateix, hi ha un petit grup de casos, menys de l'1%, que tenen un origen genètic, i per tant es consideren malalties minoritàries. En aquests casos, els pacients amb MA d'origen genètic presenten una mutació genètica que és el factor determinant per desenvolupar la malaltia, aquesta mutació s'hereta amb transmissió autosòmica dominant. Les mutacions més freqüents tenen lloc en el gen presenilina 1 (PSEN1), el gen presenilina 2 (PSEN2) i el gen de la proteïna precursora d'amiloide. L'estudi d'aquestes formes genèticament determinades suposa un model biològic excepcional per estudiar en l'humà les fases més inicials de la malaltia, especialment les fases preclíniques.

Els primers criteris pel diagnòstic clínic de la MA van ser publicats en 1984 (14). El diagnòstic definitiu de la MA restava a l'estudi neuropatològic i el diagnòstic clínic en vida se sostenia amb un quadre clínic compatible i l'exclusió d'altres

potencials causes dels símptomes. L'ús d'aquests criteris diagnòstics clínics presentava fins a un 30% d'errors diagnòstics quan es comparaven amb dades neuropatològiques, posant de manifest la necessitat de biomarcadors per donar suport al diagnòstic clínic. Els avenços en el coneixement de la malaltia i el desenvolupament tecnològic en les últimes dècades han canviat la manera de fer el diagnòstic clínic, especialment en les fases primerenques de la malaltia per la incorporació de biomarcadors, ja no d'exclusió d'altres processos sinó amb biomarcadors específics per la MA. En el context del descobriment i identificació de nous biomarcadors, cal tenir en compte que el 1998 es va establir per consens que els biomarcadors específics de la MA ha de tenir una sensibilitat major al 80% per distingir la MA de les persones sanes, i una especificitat superior al 80% també per diferenciar-la d'altres (15). De la mateixa manera, la conceptualització de la MA va canviar des d'una entitat clínica a una entitat clinicobiològica. El 2011, 100 anys aproximadament després de la descripció del primer cas de MA, es van publicar els nous criteris de la MA que inclouen la diferenciació entre la fase DCL i la demència (16,17) i inclouen també per primera vegada la fase preclínica com una part de la MA, encara en absència de símptomes (11). Als últims anys s'han publicat diversos sets de criteris que tenen en comú la inclusió de biomarcadors d'amiloïdosi, de taupatia i de neurodegeneració. Els marcadors actuals acceptats d'amiloïdosi són: els nivells baixos d'Aβ42 o ràtio Aβ42/Aβ40 en líquid cefalorraquidi (LCR), la detecció de plaques d'amiloide amb les imatges de tomografia per emissió de positrons (PET) cerebrals amb traçadors d'amiloide, i més recentment la ràtio Aβ42/Aβ40 o els nivells de ptau181 en plasma. Per altra banda, com marcadors de neurodegeneració s'accepten els nivells elevats de proteïna tau total en LCR, un patró d'atròfia característic en RM

o un patró d'hipometabolisme característic en PET con 18F-fluorodexoxiglucosa (8). A més d'aquests biomarcadors ben establerts, altres biomarcadors s'estan estudiant com complementaris per estudiar aspectes com la degeneració de la substància blanca (ex. nivells de cadenes lleugeres de neurofilaments (NfL)), la neuroinflamació i activació astròglial (ex. nivells de la proteïna quitinasa-3-similar-1 (YKL-40)), la pèrdua sinàptica (ex. nivells de proteïna 14-3-3 (14-3-3)), l'activació i proliferació astrocítica (ex. nivells proteïna acídica fibrilar glial (GFAP)), la degradació de proteïnes al proteasoma (ex. nivells d'Ubiquitin carboxy-terminal hydrolase L1 (UCH-L1)), etc. Com es pot veure en la Figura 2, cadascú dels biomarcadors segueix un curs diferent al llarg de la MA, amb diferent utilitat en cadascuna de les fases de la malaltia.

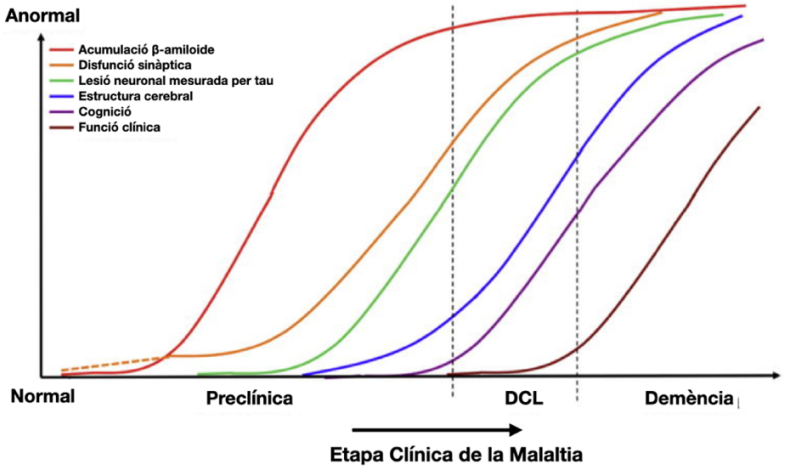

Figura 2: Mostra la trajectòria temporal dels biomarcadors claus de la malaltia d'Alzheimer, per cada una de les fases d'evolució de la malaltia. Figura adaptada de (11,18).

En aquesta tesi, de les diferents tècniques de diagnòstic de la MA, ens centrarem especialment en la RM estructural, que és una tècnica per detectar i avaluar la

presència d'atròfia en diferents estructures cerebrals. L'hipocamp és una de les estructures més afectades a conseqüència de la MA, tant precoçment com en estadis més avançats, actualment l'atròfia de l'hipocamp està inclosa en els criteris de diagnòstic de la MA acceptats i prèviament mencionats. Més enllà de l'hipocamp, hi ha uns patrons d'atròfia de substància grisa de les regions corticals ben definits per la MA. Els pacients amb MA presenten una atròfia majoritàriament temporal i parietal posterior en la RM (19–21). Les imatges de RM permeten la detecció dels canvis en la substància grisa en les àrees corticals i subcorticals associades a la MA, fins i tot en etapes prodròmiques (22). A més a més, cal destacar que les imatges de RM permeten fer un seguiment de la progressió de la malaltia, per exemple, les regions com l'hipocamp, l'escorça entorrinal i el precúneus presenten una atròfia que permet fer aquest seguiment amb precisió (23,24). Aquests patrons d'atròfia característics de la MA mostren la utilitat d'ajudar en el seguiment de la malaltia i podrien ser de gran utilitat en el diagnòstic clínic dels diferents subtipus de MA. Tot i això, la seva utilitat en detectar els pacients amb MA en fase preclínica està menys establerta (22). En la Figura 3, es pot observar l'atròfia característica per les persones amb MA i s'observa que és diferent les persones sanes.

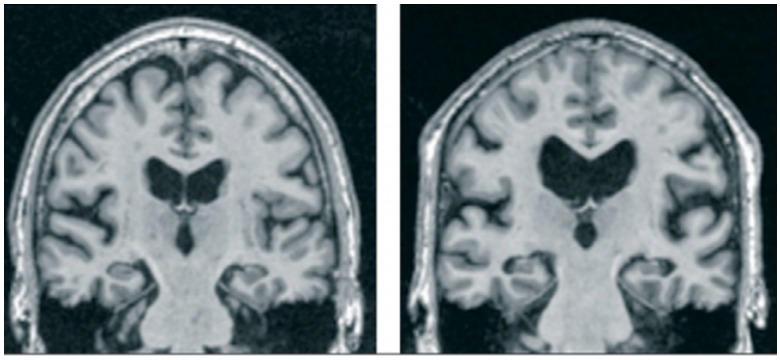

Figura 3: Mostra la ressonància magnètica de cervell de dues persones adultes per observar l'atrofia cerebral causada per la malaltia d'Alzheimer. D'esquerra a dreta, primer trobem un adult sa sense atrofia cerebral, en canvi el segon adult està diagnosticat amb malaltia d'Alzheimer, i mostra atrofia cerebral. Figura adaptada de (18).

1.3 DEMÈNCIA FRONTOTEMPORAL

La DFT és la segona demència neurodegenerativa més freqüent en menors de 65 anys, darrere de la MA, englobant aproximadament el 10% en aquest rang de població dels casos de demència (28–30). Actualment, es considera una malaltia amb una prevalença aproximada entre 15-22 per 100.000 persones, tot i que es creu que podria estar infradiagnosticada i els números podrien ser més elevats (29,31). La DFT és un terme paraigües que engloba un conjunt d'entitats neurodegeneratives que provoquen la pèrdua progressiva de neurones que té lloc principalment en els lòbuls frontal i temporal. La DFT, que ha tingut diversos noms en el transcurs de la història, va ser descrita per primer cop per Arnold Pick en 1892 (32), per això també és coneguda com a Malaltia de Pick. Arnold Pick va descriure diversos pacients que presentaven trastorns de llenguatge i alteracions

conductuals amb una marcada atrofia frontal i temporal en el cervell en les seves autòpsies.

La DFT és un trastorn progressiu que es caracteritza a clínicament per canvis conductuals i disfunció cognitiva en què predomina la disfunció executiva i els problemes de llenguatge. És un grup de trastorns clínicament, neuropatològicament i genèticament heterogeni. La DFT d'origen genètic suposa aproximadament un 15% dels casos (5-30% segons les sèries) (33,34). La majoria d'aquests casos són deguts a l'herència autosòmica dominant d'expansions patològiques en el chromosome 9 open reading frame 72 (C9orf72), mutacions en el gen de granulina (GRN) o de la proteïna tau associada a microtúbuls (MAPT) (30). Les formes genètiques de DFT permeten estudiar els canvis que tenen lloc al cervell dels portadors de mutacions patogèniques anys abans de l'inici dels símptomes. En el cas de la DFT d'origen genètic el diagnòstic es pot fer a través d'un test genètic per detectar si la persona és portadora d'algunes de les mutacions que origina la DFT. En el cas de la DFT esporàdica el diagnòstic definitiu requereix l'estudi neuropatològic, que habitualment només es fa post mortem. Pel diagnòstic en vida s'estableixen dues categories diagnòstiques: probable o possible (36). El diagnòstic possible es basa en elements clínics. Un perfil d'atròfia característic amb afectació predominant dels lòbuls frontal i/o temporal en la neuroimatge estructural o bé un hipometabolisme o hipofunció d'aquestes àrees en neuroimatge nuclear dona suport al diagnòstic de DFT probable. Actualment, no hi ha biomarcadors validats del procés neuropatològic subjacent. Bioquímicament, els nivells de NfL en LCR i sang, marcadors de lesió axonal podrien ser útils en la DFT per diferenciar-la de processos psiquiàtrics i

per avaluar la seva progressió (37–39). De manera similar a la MA, en la DFT s'ha definit un ordre temporal teòric segons el qual els diferents biomarcadors s'alterarien durant el transcurs de la malaltia, incloent-hi també la fase preclínica, es poden observar en la Figura 4.

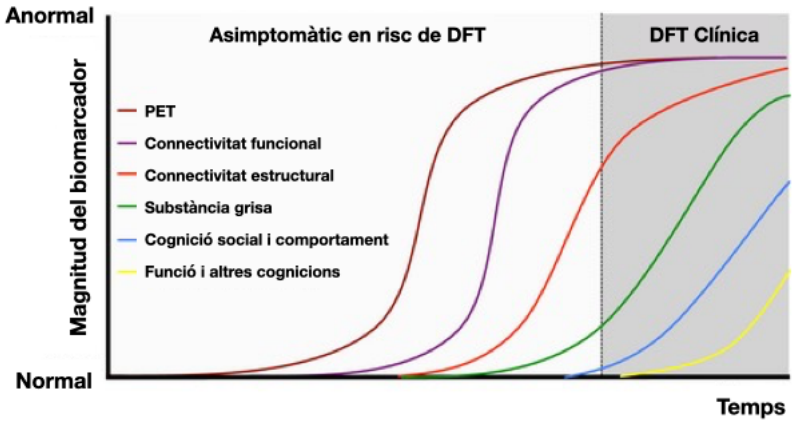

Figura 4: Mostra la trajectòria temporal dels biomarcadors claus de la demència frontotemporal, per cada una de les fases d'evolució de la malaltia. Figura adaptada de (40)

Clínicament, existeixen dos grans subtipus de DFT: la variant conductual (vcDFT), que principalment afecta la conducta i la personalitat de les persones que la pateixen, i les afàsies progressives primàries (APP), en aquesta la principal afectació acostuma a ser una alteració del llenguatge. Les APP es poden dividir en 4 subtips: la variant semàntica (vsAPP), on les persones que la pateixen presenten un llenguatge fluent, una anòmia severa i una pèrdua de la capacitat per identificar el significat de les paraules; la variant no fluent (vnfAPP), en aquest cas es caracteritza per presentar dificultats en l'emissió del llenguatge, agramatisme i apràxia de la parla; la variant logopèdica (vlAPP), que presenta com a característica principal les pauses constant en la parla, la dificultat per trobar les paraules i dificultats per repetir frases, habitualment amb una MA

subjacent. Finalment, hi ha alguns pacients amb APP que no es poden classificar en algun dels grups mencionats anteriorment i s'anomenen APP inclassificables o mixtes. En aquesta tesi, a causa de les característiques de la mostra, s'estudien les variants vcDFT, vsAPP i vnfAPP. En la Figura 5, es pot observar l'atròfia característica de cada una de les variants mencionades (30,41).

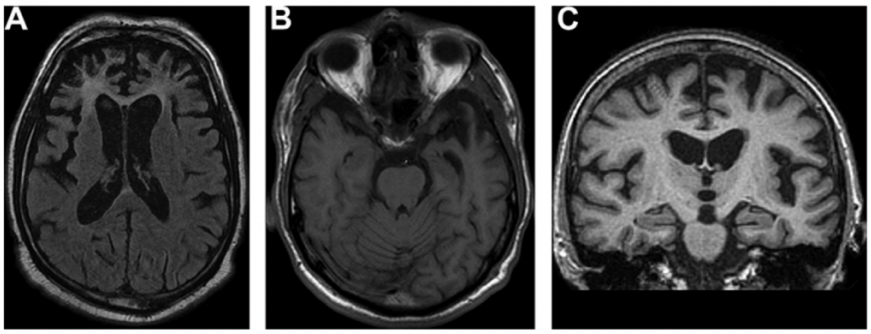

Figura 5: Mostra la ressonància magnètica de cervell de tres persones adultes per observar l'atròfia cerebral causada per la demència frontotemporal i com es diferencia en cada una de les variants clíniques. A) Pacient amb demència frontotemporal amb la variant conductual que presenta atròfia frontal B) Pacient amb demència frontotemporal amb la variant semàntica que presenta atròfia al temporal a l'hemisferi esquerre C) Pacient amb demència frontotemporal amb la variant no fluent que presenta atròfia frontal inferior de l'hemisferi esquerre i temporal superior. Figura adaptada de (30).

1.4 DIAGNÒSTIC DIFERENCIAL ENTRE LA DEMÈNCIA FRONTOTEMPORAL I LA MALALTIA D'ALZHEIMER

La superposició de símptomes amb altres malalties, especialment psiquiàtriques i la manca de marcadors de procés fisiopatològic, com s'ha mencionat abans, fa que amb freqüència pacients amb DFT pateixen un retard diagnòstic notable.

També persones amb MA sobretot menors de 65 anys, arriben a les consultes especialitzades aproximadament 3 anys després de l'inici dels símptomes (3). Així mateix, és freqüent la confusió entre la DFT i la MA, especialment en formes de presentació atípiques de la MA (42–44). És per això que hi ha una necessitat d'identificar biomarcadors específics de la DFT, per poder facilitar el seu diagnòstic. Ja s'ha vist que en el diagnòstic diferencial entre la DFT i la MA, els biomarcadors químics poden ser de gran ajuda (45), però no sempre estan disponibles o la presència de patologia concomitant podria fer-los resultar no concloents.

La combinació de neuroimatge, proves cognitives, i biomarcadors bioquímics podria millorar el diagnòstic de la DFT i de les seves diferents expressions clíniques. Els nivells de NfL en LCR i sang, són possibles biomarcadors de DFT molt prometedors, ja que indiquen dany neuroaxonal. Tot i això, podrien ser marcadors de neurodegeneració inespecífics, que també poden estar alterats amb pacients amb MA o en altres malalties neurodegeneratives (46–50). Així, tot i presentar resultats prometedors amb diferenciar la DFT de persones sanes, a l'hora de fer un diagnòstic diferencial amb la MA podrien no ser els més adequats. Els pacients amb DFT presenten nivells més alts de NfL respecte als pacients amb MA, tot i que hi ha un grau de superposició destacable (51,52). Per aquest motiu, biomarcadors de neuroimatge podrien ser d'ajuda a l'hora de realitzar un diagnòstic diferencial entre la DFT i la MA (53–55).

Els estudis de neuroimatge, especialment de RM estructural, poden millorar la precisió diagnòstica diferencial de la DFT i la MA quan els biomarcadors bioquímics no donen resultats concloents, ja que permeten identificar patrons

anatòmics característics de cada una de les demències (41) on la MA presenta una atròfia majoritàriament temporal i parietal posterior, i la DFT es presenta essencialment alteracions temporals i frontals (30,50). Tot i això, és necessari estudiar la RM a escala individual, ja que aquests patrons característics de cada una de les demències, poden ser patrons en l'àmbit grupal, però no sempre són certs per a tots els pacients, pel fet que sobretot la DFT és molt heterogènia. Per una altra part, l'estudi de l'heterogeneïtat que s'observa clínicament podria donar pistes sobre els condicionants tant del fenotip, com de la progressió de la malaltia i podria ser clau per fer una avaluació personalitzada del cas. Finalment, actualment tant per la MA com per la DFT no disposem de marcadors de progressió o pronòstic a la DFT, cosa que limita la informació personalitzada al pacient i el desenvolupament d'eines terapèutiques.

1.5 RESSONÀNCIA MAGNÈTICA EN L'ESTUDI DE LA MALALTIA D'ALZHEIMER I LA DEMÈNCIA FRONTOTEMPORAL

La RM és una tècnica no invasiva que utilitza el magnetisme per crear imatges de les estructures del cos. És una tècnica molt habitual per obtenir imatges del cervell. Aquesta tècnica és no ionitzant, ja que no fa servir radiació com podria ser en el TC o el PET, i la majoria dels hospitals tenen accés a un sistema d'adquisició de RM. Dins d'un escàner de RM, s'emeten polsos de radiofreqüència en presència d'un camp magnètic molt fort (d'entre 1,5 i 7 Tesla) i aquests provoquen moviments d'excitació i relaxació en els nuclis d'hidrogen que es poden mesurar com a corbes de relaxació en el temps a les antenes receptores,

anomenades T1 i T2. Els diferents teixits tenen diferents propietats magnètiques i això ens permet generar imatges de l'anatomia i la funcionalitat de l'estructura o l'òrgan estudiat. Hi ha diverses modalitats de ressonància magnètica cerebral, que depenen de la programació de la seqüència de polsos i de les mesures de T1 i/o T2. Les més importants són: la RM estructural que proporciona una imatge d'alta qualitat que permet observar detalls de l'anatomia del cervell i que és la que s'estudia en aquesta tesi; la RM funcional, que permet estudiar l'activitat cerebral; i finalment, la RM de difusió que mesura l'anisotropia de les molècules d'aigua, això ens permet estimar els tractes de les fibres cerebrals.

La física que hi ha darrere és que la RM estructural cerebral és que la magnetització dels teixits fa que varin de direcció, amb el camp magnètic que genera l'imant que envolta el tub de l'escàner. Quan es deixa de tenir camp magnètic es produeix la relaxació magnètica, és a dir, retornar al seu estat inicial abans d'haver estat alterat. Aquesta fase és la que ens permet obtenir realment les imatges que ens permeten estudiar el cervell. Cada teixit torna al seu estat en una velocitat diferent i aquesta informació és recollida, ja que es genera una ona magnètica que ens permet aconseguir aquesta informació que un cop es reconstrueixi ens permetrà identificar els diferents teixits en la imatge. En les imatges T1 (Figures 3 i 5), la substància grisa es correspon a la tonalitat de gris fort, mentre que la substància blanca al gris fluix. Finalment, el negre correspon al LCR i el blanc al crani. Depèn de la seqüència en què estigui potenciada la imatge la correspondència de colors i teixits serà diferent. Actualment, s'estan utilitzant cada cop més els escàners de RM de 3T (abans s'utilitzaven més el 1,5T que tenen una resolució menor) que permeten diferenciar la substància grisa, la

blanca i el LCR sense dificultats, permeten obtenir valors d'aquestes imatges cerebrals.

Per poder avaluar l'atròfia cerebral (és una prova de la neurodegeneració), i fer-la servir com una eina complementària pel diagnòstic diferencial de la MA i la DFT, és necessari tenir uns valors numèrics que permetin quantificar els aspectes visuals que s'observen. L'atròfia es pot mesurar visualment, amb escales que permeten categoritzar segons el rang d'atròfia que es presenta, o amb procediments de processament d'imatges semiautomàtics. Aquests procediments semiautomàtics que són els que fem servir per a la present tesi, es poden realitzar amb diversos softwares (FreeSurfer (https://surfer.nmr.mgh.harvard.edu), FSL (https://fsl.fmrib.ox.ac.uk), SPM (www.fil.ion.ucl.ac.uk/spm)) i s'ha demostrat que les mesures quantitatives que proporcionen tenen una correlació alta amb les mesures histològiques (56). Per poder estudiar l'atròfia en detall, aquests programes fan el processament semiautomàtic de les imatges de RM estructural per estimar el volum de substància grisa i el gruix cortical i obtenir valors globals i regionals, mitjançant atles que ens permetin identificar cada una de les regions. Per regions corticals, és habitual dividir l'escorça cerebral segons l'atles Desikan (57), que ens proporciona un mapa de 68 regions corticals de cervell (Figura 6). Mentre que per estudiar les regions subcorticals l'atles Aseg (58), és el més comú i ens permet tenir un mapa de 37 regions subcorticals. Hi ha altres atles que ens permeten segmentar el cervell en diferents granularitats, utilitzar un atles o un altre dependrà de l'objectiu de l'estudi.

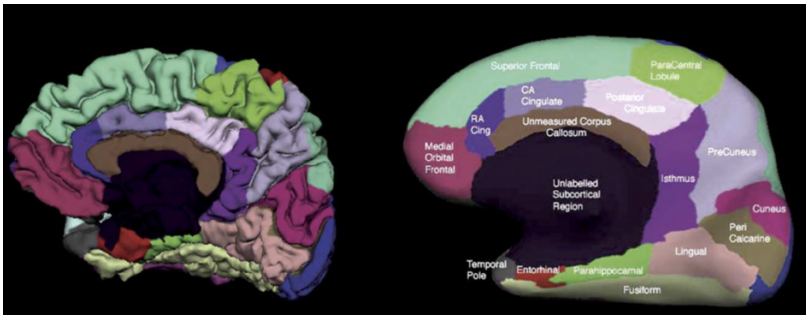

Figura 6: Representacions de les regions corticals segons de l'atles Desikan amb vista medial. Esquerra mostra la representació pial i la dreta mostra el cervell inflat conjuntament amb els noms de les regions que es veuen en aquesta vista. Figura adaptada de (57)

L'atròfia de l'hipocamp és una característica diagnòstica de la MA acceptada, que es pot avaluar amb mètodes semiautomàtics que ens permetin calcular el volum de l'hipocamp per poder estudiar si hi ha una disminució del seu volum, que ens estaria indicant la presència d'atròfia en aquesta regió. Tot i ser una mesura acceptada en el diagnòstic de la MA, pot ser que serveixi per diferència persones amb MA respecte persones sanes, però no suficient per fer un diagnòstic diferencial amb DFT o un diagnòstic de la MA amb un estadi precoç (59). Per aquest motiu necessitem estudiar totes les regions del cervell, ja que ens aportarà la informació necessària que podria fer realitzar el diagnòstic diferencial. Quan es vol estudiar totes les regions del cervell com un conjunt i estudiar les seves relacions i com interaccionen entre elles per poder explicar les dues demències o estudiar la progressió que presenten al llarg del temps conjuntament la seva variabilitat es necessiten eines matemàtiques avançades. Per poder aconseguir aquest diagnòstic diferencial de la DFT i la MA, hi ha un creixement d'eines estadístiques avançades i models d'intel·ligència artificial que permeten l'estudi detallat de tota la informació que aporten les imatges o la combinació d'aquestes amb altres proves accessibles (30,60–62).

1.6MODELS PREDICTIUS

El 1993 Geisser defineix els models predictius o models de predicció com "el procés pel qual un model es crea o es tria per intentar predir millor la probabilitat d'un resultat" (63). Aquesta definició es pot interpretar com que els models predictius són processos de desenvolupament d'una eina o model matemàtic que genera una predicció precisa per englobar els més actuals (64). En els fons els models predictius són un conjunt de tècniques matemàtiques i estadístiques que permeten predir el comportament de certa variable en funció d'un o uns esdeveniments coneguts. Analitzant les dades històriques i les actuals i generant un model matemàtic es poden predir resultats del futur. Fet que fa que estiguin molt presents en el nostre dia a dia i siguin de rellevància per la ciència. Són d'utilitat pel cercador Google, les xarxes socials, i en context clínic ens podrien ajudar a respondre la pregunta de si una persona patirà una malaltia concreta. Poden ser de gran utilitat per estudiar malalties i ens poden guiar cap a una medicina personalitzada en permetre definir quins tractaments mèdics poden ser més adients segons les característiques del pacient, estudiar la variabilitat, o predir quina evolució pot tenir un pacient en funció de les seves característiques. Ara bé, aquests models també poden generar prediccions inexactes o donar respostes incorrectes. Quan els models predictius fallen acostuma a ser per algun d'aquests motius (1) un preprocessament incorrecte de les dades, (2) una validació inadequada de les dades, (3) una extrapolació injustificada, per exemple, portar les dades en un espai que no és el correcte, o (4) el sobreajustament del model (64). Per tant, moltes de les vegades que fallen els models recau en les dades, és per això, que és molt important conèixer les dades

i saber quines són les limitacions que comporten si volem obtenir models predictius fiables. Pel context d'aquesta tesi, ens centrarem en els models predictius aplicats en casos clínics.

Els models predictius engloben des de la regressió lineal fins a la intel·ligència artificial. Segons el disseny de l'estudi, es poden crear models amb dades transversals, és a dir, quan es disposa d'una única visita per participant, o amb dades longitudinals, quan per cada un dels participants tenim una visita inicial i d'altres successives que ens permeten estudiar la seva evolució al llarg del temps. Depèn de l'estudi, serà més adient fer estudis transversals o longitudinals segons la hipòtesi que es tingui. Tot i això, els estudis longitudinals recullen dades en diversos moments de múltiples participants, per tant, són difícils i costosos, però són àmpliament reconeguts com a recursos necessaris per entendre les malalties neurodegeneratives (65). En comparació amb els enfocaments transversals, els estudis longitudinals proporcionen una potència estadística més gran reduint l'efecte de confusió de la variabilitat entre subjectes (66). Per estudiar dades longitudinals la tècnica més establerta és el model d'efectes mixtos lineals (EML), aquests models ofereixen un marc potent i versàtil per analitzar les dades longitudinals. És més adequada que altres tècniques més clàssiques com podrien ser l'anàlisi de mesures repetides de la variància (ANOVA) o l'anàlisi transversal dels canvis percentuals (60,67,68).

Un cop tenim les dades modelitzades, se segueix amb un estudi de la interferència dels resultats, que permeten avaluar les hipòtesis que es tenen per analitzar si es compleixen o no. Estadísticament, es pot estudiar la mateixa hipòtesi des de dos enfocaments diferents: (1) l'enfocament freqüentista, el més utilitzat

històricament que estableix el llindar del p valor de 0,05 per saber si és estadísticament significatiu i (2) l'enfocament bayesià que en aquest cas estudia les distribucions de probabilitat de les mostres amb probabilitats condicionals de valors coneguts. L'enfocament freqüentista en termes generals es basa en les distribucions de mostreig i en el Teorema Central del Límit (69,70). En aquest cas, els paràmetres poblacionals d'interès són tractats com valors fixos. Contràriament, l'enfocament bayesià estima els paràmetres a partir de la distribució de la població un cop es dona l'evidència amb les dades observades (69,71). Per tant, es tracten els paràmetres d'interès com variables aleatòries que es poden descriure amb distribucions de probabilitat. L'enfocament bayesià es basa en el Teorema de Bayes i es basa en l'estudi de la distribució de les dades ja existents, nomenades "prior", per poder predir el comportament futur de dades noves (72). Cada opció té els seus punts forts i febles, però les diferències en aplicacions en el camp de les malalties neurodegeneratives no ha estat molt estudiat. En termes generals, la virtut més gran de l'enfocament freqüentista és el rigor i precisió extrema en la hipòtesi concreta que s'està estudiant. I la virtut més gran de l'enfocament bayesià és que permet una interpretació realment probabilística, ja que proporciona respostes directes a preguntes sobre la magnitud probable dels efectes d'interès i, per tant, permet comparar hipòtesis d'una manera senzilla i intuïtiva (72,73).

Els models predictius no solament ens permeten predir com evolucionaran els pacients amb els anys o en funció d'alguna altra variable. Tot i que aquesta és una de les principals utilitats d'aquests models. Ens permeten portar un seguiment de l'evolució de les malalties, amb tots els beneficis que comporta. Aquest

seguiment, avui en dia, és més necessari que mai, ja que permet avaluar l'eficàcia de fàrmacs o proporcionar un pronòstic precís. Per exemple, ens podria ajudar a identificar el moment idoni per iniciar el tractament i controlar la seva resposta (74). Els models predictius, que permeten realitzar estimacions en funció del temps són de gran importància per entendre la progressió de la malaltia i comparar l'estat del cervell (o altres variables, però en aquesta tesi ens centrem en les RM) entre pacients en diferents estadis de la malaltia (75–77). Tanmateix, aquests models poden generar prediccions imprecises, ja que suposen que tots els grups clínics (per aquesta tesi pacients amb MA, pacients amb DFT i persones sanes) estan ben definits i són iguals, quan biològicament sovint són molt heterogenis. Aquest enfocament ha permès detectar efectes de grups clínics, sobretot entre pacients i persones sanes, però quan es volen estudiar diferències entre grups, aquesta filosofia pot suposar tot un repte i un problema, ja que no té en compte que hi pot haver superposició de símptomes o patrons (78–80). La Figura 7 representa la base teòrica d'aquesta filosofia (Figura 7A) i alhora el que es troba en la pràctica clínica (Figura 7D), on hi ha superposicions de símptomes i patrons, co-patologies, etc. El que sembla un impediment per estimar aquests models amb precisió, actualment s'ha convertit en un gran avantatge per avançar cap a la medicina personalitzada. Podem assumir que els grups clínics no són homogenis, i estudiar aquesta heterogeneïtat que pot ser deguda a: (1) heterogeneïtat clínica, heterogeneïtat a conseqüència de diferents perfils de símptomes que es classifiquen sota el mateix trastorn. Un clar exemple és la DFT, ja sigui per les seves expressions clíniques (vcDFT, vsAPP, vnfAPP, vlAPP) com per les seves diferents causes genètiques (C9orf72, GRN, MAPT). (2) Heterogeneïtat biològica, heterogeneïtat induïda per diferents predisposicions biològiques que convergeixen en els mateixos símptomes, per exemple podrien

ser les diferents mutacions que causen MA o DFT. Finalment, (3) heterogeneïtat ambiental, diferents esdeveniments ambientals que causen (o eviten) els mateixos símptomes. Estudiar les desviacions que presenten els pacients de la norma, ens pot permetre avaluar la gravetat de la malaltia, la variabilitat cognitiva i obtenir un estudi personalitzat de l'evolució de cada pacient. En el cas de la MA i la DFT, aquestes mostren una heterogeneïtat individual relativament alta en la presentació i la taxa de progressió que és rellevant per entendre millor la patogènesi d'aquestes malalties, i predir-ne la progressió i, potencialment, l'efecte dels tractaments (81).

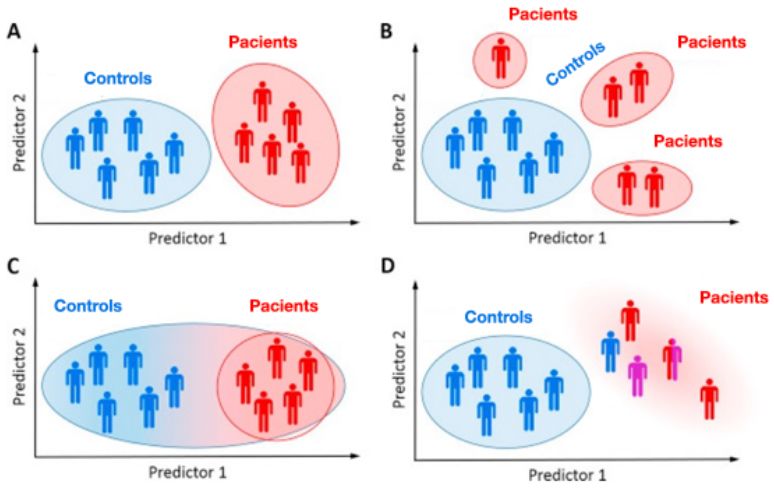

Figura 7: Representació dels diferents enfocaments dels grups clínics, en aquest cas entre persones sanes i pacients, però és extrapolable a més grups. A) Enfocament clàssic de casos i persones sanes on se suposa que cada grup clínic està ben definit. B) La població clínica pot estar formada per múltiples grups, cadascun amb una patologia diferent. C) La variació relacionada amb la malaltia es pot relacionar amb variació de les persones sanes. D) El grup clínic pot ser difús i heterogeni a conseqüència d'un diagnòstic erroni, de comorbiditats o de co-patologies. Figura adaptada de (78).

1.7 APRENENTATGE AUTOMÀTIC

Els inicis de la ciència computacional daten de 1950 quan Alan Turing va fer pública la següent pregunta "Les màquines poden pensar?" en un seminari on presentava la seva investigació (82). En aquell moment encara no s'havia desenvolupat la intel·ligència artificial, però sí que es considera un punt d'inflexió o, per molts, el seu naixement. Malgrat els anys que han passat, la pregunta continua sent vigent. Actualment, la intel·ligència artificial es podria definir com una ciència que permet imitar les capacitats humanes per resoldre problemes i la presa de decisions. És una definició volàtil, ja que en les últimes dècades han sorgit diferents definicions o han anat evolucionant. El terme intel·ligència artificial és molt ampli, engloba diferents branques dins d'aquesta disciplina, com l'aprenentatge automàtic –conegut també en anglès com *machine learning*–, i l'aprenentatge profund –conegut com a *deep learning* en anglès. Aquestes dues disciplines estan formades per algorismes d'intel·ligència artificial que permeten realitzar prediccions o classificacions basades en un conjunt de dades. En aquesta tesi ens centrem en l'aprenentatge automàtic.

L'aprenentatge automàtic va ser definit l'any 1959 pel científic Arthur Samuel com "el subcamp de la informàtica que dona als ordinadors la capacitat d'aprendre sense ser programats explícitament" (83). L'aprenentatge automàtic es basa en aquest concepte, ja que és una disciplina científica que desenvolupa models estadístics i algorismes que utilitzen els sistemes computacionals per dur a terme de manera eficaç una tasca específica basant-se en patrons i inferència de les dades, i millorant progressivament la seva precisió. L'objectiu principal és permetre que els ordinadors aprenguin automàticament, sense fer ús

d'instruccions humanes explícites. I per aconseguir-ho se segueixen normalment 3 passos estàndards: (1) Procés de decisió, les dades que s'introdueixen a l'algorisme permeten dur a terme una estimació de quin patró segueixen, amb aquesta informació l'algorisme és capaç de fer una classificació o predicció. (2) Funció d'error, s'avalua l'error de la predicció que ha dut a terme l'algorisme fent servir les dades introduïdes. Finalment, (3) optimització del model, s'analitza la qualitat de les prediccions, és a dir, si el model és capaç d'ajustar-se a les dades introduïdes. El que es pretén en aquest pas és reduir la discrepància entre l'exemple conegut (les dades introduïdes inicialment) i l'estimació feta. Aquest pas s'acostuma a repetir fins que s'obté la millor precisió possible.

Si es vol avaluar el model d'intel·ligència artificial, es necessita realitzar dues fases, una primera fase que és el que s'anomena entrenament i la segona fase que és el testatge. Això ens permetrà avaluar el model amb unes dades diferents de les que s'han fet servir per establir els paràmetres del model. Així, les dades es divideixen en dues parts. Una part de les dades es farà servir per entrenar el model i l'altra per avaluar-ne la fiabilitat o precisió. En cas de no procedir a fer la divisió dels dos conjunts de dades, ens podem trobar amb el problema de sobre ajust, que és un problema metodològic greu en els algoritmes d'intel·ligència artificial. Si s'avalua el model amb les mateixes dades que s'han utilitzat per calcular els paràmetres, s'obté una puntuació sobre optimista, ja que repeteix les etiquetes ja vistes, però no es podria avaluar si el model és útil per predir futures dades (84,85). Tanmateix, en molts casos, la divisió de les dades en dos grups no és suficient, ja que molts models necessiten avaluar quins són els paràmetres de les funcions internes del model pel conjunt de dades estudiades. És per això que

en molts casos es recomana realitzar una tercera divisió de les dades, el que s'anomena conjunt de dades de validació per resoldre el problema. El conjunt de dades de validació avalua els paràmetres òptims que ha de tenir la funció i les dades del testatge avaluen el model. Naturalment, en dividir les dades disponibles en tres conjunts, reduïm dràsticament el nombre de mostres que es poden utilitzar per entrenar el model, i els resultats poden dependre d'una elecció aleatòria particular pel conjunt de les dades estudiades. Per solucionar aquest problema, es du a terme l'estratègia del procediment de validació creuada (Figura 8), aquesta estratègia consisteix a eliminar el conjunt de dades de validació, però no la seva funció. L'enfocament més bàsic (Figura 8), és l'anomenat "k-fold" validació creuada, on el conjunt d'entrenament es divideix en k conjunts més petits (on k depèn de les dimensions dels conjunts). Aquest procediment consisteix a entrenar el model emprant els k-1 conjunts de les dades, i l'avaluació del model es realitza en les dades del conjunt restant. Per tant, les dades que entren el model en cap cas són les que es fan servir per a la validació. Aquesta divisió de les dades es fa repetides vegades, fent que totes les dades formin part de les dades d'entrenament i del conjunt de testatge, com s'observa en la Figura 8, i la mesura del rendiment que s'informa del model és la mitjana de tots els valors calculats. Aquest enfocament pot ser computacionalment costós, però permet fer l'entrenament sense reduir el conjunt de dades disponibles i fa que els models siguin precisos, extrapolables i vàlids (84,86,87).

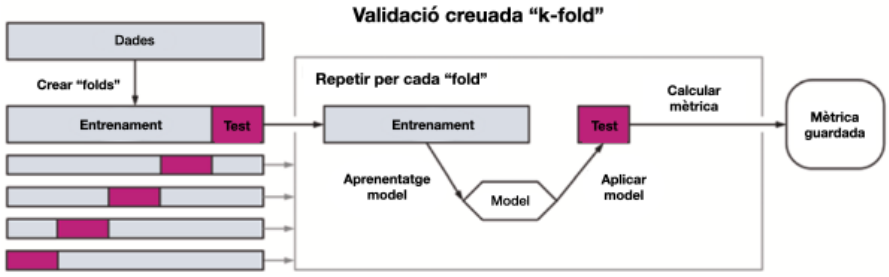

Figura 8: Esquema del procediment de la validació creuada "k-fold". S'observa que el conjunt de dades es divideix en k conjunts que es distribueixen segons conjunt entrenament i testatge aleatòriament. Figura adaptada de (85).

Els algorismes d'aprenentatge automàtic es poden classificar en 3 grups: aprenentatge supervisat, no supervisat, i semi supervisat, que és la combinació dels dos (88,89). En tots els casos es disposa d'una sèrie d'exemples o mostres, cada un amb unes determinades característiques. En l'aprenentatge supervisat, el conjunt de dades de l'entrenament estan etiquetades, per tant, l'algoritme aprèn d'exemples etiquetats. A nivell pràctic, el conjunt de dades s'estructura amb una matriu X (que no té definides les dimensions) on s'introdueixen les dades numèriques de les característiques que es necessiten per la predicció i el vector de Y on s'introdueixen les etiquetes. Els algoritmes de classificació supervisats engloben alhora dues categories principals: la regressió i la classificació. En el cas dels algoritmes de regressió, les dades que retorna l'algorisme poden tenir qualsevol valor numèric dins d'un interval, mentre que, en els algorismes de classificació, les prediccions es restringeixen a un conjunt limitat de valors (88). Posem un exemple pels dos casos, si suposem que en tots dos la matriu X són característiques mèdiques de MA o DFT, en un algorisme de classificació, podem intentar predir si aquests pacients tenen la malaltia o no. D'altra banda, en el cas de la regressió, el model avalua els valors continus per realitzar una predicció segons aquests valors continus, per exemple el valor individual de substància

grisa en funció dels anys de malaltia. Els algoritmes de classificació automàtica supervisats més coneguts i utilitzats en conjunts de dades clíniques són la màquina vectorial de suport (MVS) – coneguda com *support vector machine* en anglès –, la regressió lineal i logística o els arbres de decisió, entre d'altres. En l'aprenentatge no supervisat, s'utilitzen dades no etiquetades i la finalitat és trobar similituds o diferències entre les característiques que ens permetin identificar patrons o grups de dades sense cap mena d'interferència humana. Seguint la notació algebraica de l'exemple anterior, el vector Y en aquest cas no existeix i les úniques dades són les característiques que formen la matriu X, no hi ha cap mena de variable que pugui etiquetar les dades en grups predefinits (84). Un exemple és agrupar els pacients en subgrups segons les seves característiques biològiques, cognitives o clíniques. Posteriorment, podem intentar interpretar si aquests subgrups es poden relacionar, per exemple, en si respondran a un medicament o no, en aquest cas tindríem la finalitat de predir si necessiten el medicament o no. Els algoritmes de classificació automàtica no supervisats més coneguts i utilitzats per dades clíniques són anàlisi de clústers o l'anàlisi de components principals. Finalment, l'aprenentatge semi supervisat és la combinació de les dues metodologies anteriorment explicades. En aquesta metodologia, en la fase d'entrenament part de les dades estan etiquetades mentre que les altres no. Així que les dades etiquetades serveixen per guiar la classificació de les no etiquetades. Aquest mètode acostuma a ser l'opció escollida si etiquetar totes les dades (agrupar-les en grups) té un cost molt elevat.

1.8 UTILITAT DE L'APRENENTATGE AUTOMÀTIC EN LA CLÍNICA

L'aprenentatge automàtic ha revolucionat molts camps i poden ser de gran utilitat en el desenvolupament de la cura de la MA, la DFT i altres afeccions cròniques. Aquestes tècniques es beneficien de l'accés a grans quantitats d'informació sobre els pacients, i són capaces d'aprendre i construir models robustos i d'alt rendiment, que poden ajudar a identificar marcadors de risc, identificar patrons amb utilitat diagnòstica, modelar la progressió de les malalties i fins i tot suggerir intervencions de medicina de precisió per a pacients a escala individual de manera ràpida (50). Tots i els prometedors avantatges, la metodologia està en un estat inicial, i s'han de crear algoritmes interpretables perquè siguin transferibles a la clínica i que millorin les eines disponibles.

Els algoritmes d'aprenentatge automàtic presenten molts avantatges per les malalties neurodegeneratives, en conseqüència per la MA i la DFT (90). Tot i això, els treballs publicats en aquesta àrea no es distribueixen uniformement, s'ha investigat molt en mètodes per la classificació entre pacients de MA i persones sanes, però no hi ha gaires estudis que se centrin a aprofundir en els avantatges d'aquests mètodes per estudiar el diagnòstic diferencial en les diferents demències, que és un problema clínicament rellevant (91). Els estudis recents proporcionen una evidència que sosté el paper de les tècniques d'aprenentatge automàtic que utilitzen la RM estructural (62,92,93) per donar suport al diagnòstic clínic de demències neurodegeneratives (61,94–96).

Les tècniques d'aprenentatge automàtic també ens poden ajudar a entendre la variabilitat fenotípica que presenten aquestes malalties tant en variabilitat de símptomes com d'edat d'inici o progressió i possiblement també de variabilitat en resposta terapèutica (90). En aquest sentit, l'aprenentatge automàtic no supervisat podria ser d'utilitat analitzant dades clíniques i de neuroimatge, podria identificar subtipus de MA, de DFT o caracteritzar la variabilitat individual. Així, els models d'aprenentatge automàtic ofereixen una oportunitat única per disseccionar aquestes malalties amb detall i des d'un enfocament objectiu, sense premisses clíniques preestablertes, ja que ens basem en dades recopilades sense intervenció humana (91).

En aquest context, el diagnòstic, l'anàlisi de la variabilitat i la predicció de l'evolució i la resposta terapèutica de les malalties neurodegeneratives a través dels models matemàtics és una branca d'investigació creixent, que requereix tant innovació metodològica com de models d'avaluació per l'aplicació clínica, amb una gran varietat d'aplicacions potencials. En aquest sentit, la recerca en el camp de l'aprenentatge automàtic ha d'adaptar-se a investigar els reptes clínics reals actuals; per l'altre costat la investigació clínica ha d'estar oberta als potencials beneficis de l'ús de models matemàtics, i especialment de l'aprenentatge automàtic.

CAPÍTOL 2

Hipòtesis i Objectius

2.1 HIPÒTESIS

1. La consistència dels resultats de l'anàlisi estadística segons l'aproximació freqüentista o bayesiana en bases de dades clíniques i paraclíniques de malaltia d'Alzheimer, especialment en dades longitudinals, dependrà de l'homogeneïtat de les dades.
2. Es podrà avaluar la variabilitat individual de les persones amb malaltia d'Alzheimer i demència frontotemporal amb models de predicció grupal del gruix cortical. Aquesta variabilitat es podrà relacionar amb variables clíniques i biomarcadors.

3. Les dades de ressonància magnètica estructural ens permetran classificar de forma automàtica els pacients amb malaltia d'Alzheimer i demència frontotemporal, i alhora proporcionaran mapes cerebrals que permetin la interpretació de les decisions de l'algoritme. Els estudis longitudinals milloraran el rendiment diagnòstic diferencial de la malaltia d'Alzheimer i la demència frontotemporal amb algoritmes de classificació automàtica.
4. Serà possible obtenir les probabilitats individuals de diagnòstic de la malaltia d'Alzheimer o la demència frontotemporal, i aquestes permetran identificar subjectes en la zona de baixa confiança del diagnòstic i planificar quins pacients es beneficiarien de proves addicionals.
5. Una mesura precisa de l'asimetria cerebral ens permetrà diferenciar els pacients amb demència frontotemporal respecte a pacients amb malaltia d'Alzheimer i diferenciar-ne les variants clíniques.
6. Estudis quantitatius de ressonància magnètica en algunes variants genètiques de demència frontotemporal, podrien identificar canvis d'utilitat clínica. Portadors de la mutació C9orf72, podrien presentar una pèrdua de substància blanca al tronc encefàlic per l'afectació de vies motores.

2.2 OBJECTIUS

L'objectiu general d'aquesta tesi és avaluar l'aportació dels models matemàtics avançats en les eines de diagnòstic, d'estudi de variabilitat i de progressió actuals

en la malaltia d'Alzheimer i la demència frontotemporal. Els objectius específics són:

1. Avaluar l'impacte de l'ús dels diferents enfocaments estadístics en estudis longitudinals de dades clíniques i paraclíniques de ressonància magnètica de la malaltia d'Alzheimer.
2. Caracteritzar models de gruix cortical en termes que a) permetin estudiar la variabilitat individual dels pacients amb malaltia d'Alzheimer i demència frontotemporal, b) permetin predir l'evolució dels pacients amb malaltia d'Alzheimer i demència frontotemporal amb relació al temps d'evolució.
3. Explorar i comparar la utilitat diagnòstica dels algoritmes de classificació automàtica en estudis transversals i estudis longitudinals de pacients amb malaltia d'Alzheimer i demència frontotemporal.
4. Establir la probabilitat individual per la classificació entre pacients amb malaltia d'Alzheimer, demència frontotemporal, i persones sanes per estudiar la zona de baixa confiança diagnòstica de persones amb malaltia d'Alzheimer i demència frontotemporal.
5. Definir un índex d'asimetria cerebral a partir dels valors del gruix cortical que permeti identificar persones amb demència frontotemporal i les seves variants clíniques.
6. Avaluar la pèrdua de substància blanca del tronc encefàlic en portadors simptomàtics i asimptomàtics de la mutació C9orf72 comparat amb no portadors i la seva relació amb la presència de malaltia de motoneurona clínica.

CAPÍTOL 3

Mètodes

El mètode de cadascun dels estudis es detalla en el manuscrit corresponent. Tot seguit es descriuen breument de manera general les dades utilitzades, els criteris de diagnòstic dels participants i les principals tècniques utilitzades, ja que són factors comuns en els articles que formen aquesta tesi.

3.1 PARTICIPANTS

Pel primer treball es fa servir la base de dades pública Alzheimer's Disease Neuroimaging Initiative (ADNI) (https://adni.loni.usc.edu), que és una base de

dades pública multicèntrica dissenyada per estudiar la MA. Les dades dels escàners de ressonància magnètica estructural de pacients amb MA, deteriorament cognitiu lleu (DCL) i persones sanes (CTR) de diverses visites són descarregades. Els criteris de diagnòstic (97) per cada un dels pacients és el següent:

a) MA: Persones adultes amb queixes cognitives amb Mini-Examen d'estat mental (MMSE) entre 20 i 26 i Escala de classificació clínica de demència (CDR) entre 0,5 i 1.
b) DCL: Persones adultes amb queixes cognitives amb MMSE entre 24 i 30 i CDR 0,5.
c) CTR: Persones adultes sanes sense queixes cognitives amb MMSE entre 24 i 30 i CDR 0.

Pel segon, tercer, quart i cinquè treball es fa servir dades de pacients MA, DFT, i CTR, visitats a la Unitat d'Alzheimer i altres trastorns cognitius del Servei de Neurologia de l'Hospital Clínic de Barcelona. El Comitè ètic de l'Hospital Clínic de Barcelona ha aprovat els estudis (HCB 2019/0105) i tots els pacients han signat el consentiment informat per participar. Per aquests estudis s'han fet servir les imatges de RM estructural, en els estudis segon, tercer i cinquè s'ha fet servir més d'una visita dels pacients, per tant, un estudi longitudinal, mentre que en el quart estudi solament es va fer servir la primera visita d'aquests pacients. En els estudis segon, quart i cinquè també s'han fet servir dades de biomarcadors de LCR i sang i proves cognitives d'aquests pacients. Els criteris de diagnòstic per aquests pacients ha estat:

a) MA: Pacients que complien els criteris clínics de demència lleu a causa de MA (16,17) confirmats per un perfil de biomarcadors de LCR que suggereix la neuropatologia subjacent de la MA segons National Institute on Aging/Alzheimer's Association Research Framework 2018 (13).
b) DFT: Pacients que complien els criteris clínics pel diagnòstic de diferents variants de DFT, exactament la variant conductual o els fenotips de l'afàsia primària progressiva semàntica o no fluent (36,98).
c) CTR: Persones adultes sanes amb rendiment cognitiu dins del rang normatiu.

Finalment, el sisè article solament ha estat centrat en DFT de causa genètica, per això s'ha fet servir les dades de RM i de proves cognitives del consorci Genetic Frontotemporal dementia Initiative (GENFI) (https://www.genfi.org/) que és un consorci que engloba diferents grups de centres de recerca d'Europa i el Canadà. L'Hospital Clínic de Barcelona en forma part a través d'una de les directores d'aquesta tesi la Dra. Raquel Sánchez-Valle com IP en el centre. Els comitès ètics de cada centre han aprovat els procediments i tots els pacients han firmat el consentiment corresponent. En aquest cas solament han format part de l'estudi els pacients amb la mutació del gen C9orf72, els criteris de diagnòstic dels pacients són els següents:

a) DFT: Portadors de l'expansió patogènica a C9orf72, asimptomàtics o simptomàtics amb diagnòstic clínic de DFT o esclerosi lateral amiotròfica.
b) CTR: Participants familiars de primer grau de portadors de la mutació C9orf72, no portadors de l'alteració genètica.

3.2 ADQUISISCIÓ DE LA RESSONÀNCIA MAGNÈTICA

Les dades de RM estructural del primer treball es van adquirir en diferents escàners 1,5T i 3T, dels fabricants Philips Healthcare (Koninklijke Philips NV, Amsterdam, Països Baixos), GE Healthcare Life Sciences (General Electric, Boston, MA, EUA) i Siemens Healthcare Diagnostics. (Siemens, Erlangen, Alemanya).

Pels treballs segon, tercer, quart i cinquè les imatges de ressonància magnètica es van adquirir en els escàners 3T Magnetom Trio Tim (Siemens Medical Systems, Alemanya) i la seva actualització el Prisma 3T (Siemens Medical Systems, Alemanya) de la Plataforma d'imatge per Ressonància magnètica de FRCB-IDIBAPS. Es va utilitzar les imatges de RM estructurals 3D d'alta resolució (ponderat en T1, MP-RAGE, temps de repetició = 2,30ms, temps d'eco = 2,98ms, 240 llesques, camp de visió = 256 mm, mida del vòxel = 1 ×1 x 1mm).

Finalment per l'últim treball les dades de RM estructural es van adquirir en 19 escàners de tres fabricants diferents: Philips Healthcare (Koninklijke Philips NV, Amsterdam, Països Baixos), GE Healthcare Life Sciences (General Electric, Boston, MA, EUA) i Siemens Healthcare Diagnostics. (Siemens, Erlangen, Alemanya). Els protocols d'adquisició van ser sotmesos a controls de qualitat per la seva harmonització.

3.3 PROCESSAMENT DE LES IMATGES DE RESSONÀNCIA MAGNÈTICA

El primer treball és l'únic que les dades de ressonància magnètica van estar ja processades externament, pel consorci ADNI (99).

Per la resta de treballs que formen aquesta tesi el processament de les imatges ha estat realitzat íntegrament per l'autora d'aquesta tesi. Es va utilitzar el processament disponible amb el software FreeSurfer (http://surfer.nmr.mgh.harvard.edu.sire.ub.edu/) versió 6.0 per dur a terme la reconstrucció cortical i la segmentació volumètrica de les adquisicions ponderades en T1. FreeSurfer ens permet obtenir mapes de gruix cortical i segmentar les estructures subcorticals (100,101). Amb les imatges reconstruïdes s'aconsegueixen les mesures resumides de volums mitjans del gruix cortical i la substància grisa dels dos hemisferis. Els valors per regions corticals i subcorticals que fem servir per a aquesta tesi són els dels atles disponibles a FreeSurfer (57,102). Totes les imatges i les segmentacions individuals es van inspeccionar visualment i es van corregir manualment en cas de ser necessari.

3.4 BIOMARCDORES DE LÍQUID CEFALORRAQUIDI i SANG

Els estudis segon, quart i cinquè inclouen biomarcadors de LCR i sang, els nivells d'aquests biomarcadors es van obtenir al laboratori del grup d'Alzheimer i altres trastorns cognitius de FRCB-IDIBAPS (Cellex) o al Centre de diagnòstic biomèdic de l'Hospital Clínic de Barcelona.

Pels biomarcadors de LCR, la seva extracció va ser amb una punció lumbar, posteriorment l'anàlisi dels diferents biomarcadors va ser utilitzat kits d'assaig immunosorbent lligat a enzims (ELISA) disponibles comercialment per determinar els nivells d'Aβ42, t-tau i p-tau (INNOTEST, Fujirebio Europe N.V., Gent, Bèlgica), NfL (IBL International, Hamburg, Alemanya) i 14-3-3 (CircuLex, MBL International Corporation, Woburn, MA).

En el cas dels biomarcadors de sang, la seva anàlisi va ser mitjançant Quanterix Simoa Neurology 4-Plex A (incloent-hi t-tau, GFAP, NfL i UCH-L1) i Quanterix Simoa p-tau181 Advantage V2 i V2.1 seguint el protocol del fabricant (Quanterix, Billerica, MA) i s'harmonitza els valors dels dos kits.

3.5 IMPLEMENTACIÓ DELS MODELS MATEMÀTICS

Els models matemàtics, els models d'intel·ligència artificial i les anàlisis estadístiques de la present tesi han estat dissenyats per l'autora d'aquesta tesi i implementats en els llenguatges de programació Pyhton (www.python.org) o R (https://www.r-project.org) principalment. Les versions dels programaris s'indiquen en els diferents treballs, ja que hi ha hagut actualitzacions al llarg de la tesi.

El primer i sisè treball tenen una base principalment estadística, i per això s'han dut a terme únicament amb el llenguatge de programació R, i en el cas del primer

treballa una part també amb el llenguatge Stan (https://mc-stan.org/). Pel primer treball hi ha el codi per reproduir l'estudi en obert a Github (https://github.com/Agnes2/LME-with-a-Bayesian-and-Frequentist-Approaches.git), ja que és amb dades públiques.

El segon, tercer i quart article els models d'intel·ligència artificials han estat implementats en Python amb la llibreria Scikit-learn (103), una llibreria àmpliament utilitzada i acceptada per realitzar models d'intel·ligència artificial en diversos àmbits i contextos. Es caracteritza per tenir eines simples i eficients per l'anàlisi predictiva de les dades. Per altra banda, la part més estadística i de gràfics dels treballs ha estat desenvolupada en R.

Finalment, en el treball cinquè també s'ha fet servir la combinació dels dos llenguatges de programació (Python i R). Per desenvolupar l'índex que es presenta s'ha fet amb el llenguatge Python sense fer ús de llibreries on ja havia estat implementat. Finalment, per l'estudi estadístic i de visualització s'ha fet servir funcions de llibreries ja implementades de R.

Evaluating the performance of Bayesian and frequentist approaches for longitudinal modeling: application to Alzheimer's disease

Agnès Pérez-Millan[1,2], José Contador[1], Raúl Tudela[3], Aida Niñerola-Baizán[3,4], Xavier Setoain[3,4], Albert Lladó[1,5], Raquel Sánchez-Valle[1] & Roser Sala-Llonch[2,3]✉

Linear mixed effects (LME) modelling under both frequentist and Bayesian frameworks can be used to study longitudinal trajectories. We studied the performance of both frameworks on different dataset configurations using hippocampal volumes from longitudinal MRI data across groups—healthy controls (HC), mild cognitive impairment (MCI) and Alzheimer's disease (AD) patients, including subjects that converted from MCI to AD. We started from a big database of 1250 subjects from the Alzheimer's disease neuroimaging initiative (ADNI), and we created different reduced datasets simulating real-life situations using a random-removal permutation-based approach. The number of subjects needed to differentiate groups and to detect conversion to AD was 147 and 115 respectively. The Bayesian approach allowed estimating the LME model even with very sparse databases, with high number of missing points, which was not possible with the frequentist approach. Our results indicate that the frequentist approach is computationally simpler, but it fails in modelling data with high number of missing values.

The availability of longitudinal data-repeated measures of the same subjects over time-provides the opportunity to study trajectories of disease biomarkers. This offers an unquestionable value, as measures of change and evolution can complement cross-sectional analyses—mainly based on group differences at a specific time point—into the understanding of neurological diseases and the evaluation of disease-modifying treatments. However, real-life longitudinal databases are often characterized by high levels of noise, high variability, and missing points that lead to unbalanced data. All these factors represent a challenge when creating the models and often limit their interpretability. In this context, the use of linear mixed effects (LME) models offers a powerful and versatile framework for analysing longitudinal data, being more adequate than classical approaches such as repeated measures analysis of variance (ANOVA) or cross-sectional analysis of percent changes[1–3].

In addition, when these biomarkers are obtained from neuroimaging data, there are additional challenges, as there are strong dependencies within subjects and timepoints. In this sense, besides the clear dependencies between the different measures of one subject, there are also dependencies between subjects that need to be modelled. LME models attempt to reconcile these schemes by combining fixed and random effects, where fixed effects are assumed to represent those parameters that are the same for the whole population, while random effects are group dependent variables assumed to consider the variance in the data explained over time and subject. In our case, the random effects will take into account the variability of the non-independent measures from different subjects[4–6].

After data modelling, LME models are usually followed by statistical inference procedures, which allow the researcher to generate questions about the model and to further evaluate their statistical significance and clinical relevance. In this sense, while statistical significance is well established to p-values < 0.05, or equivalent, the assessment of clinical relevance has not yet a standard analysis[7]. It has been suggested that clinical relevance can never be determined form p-values alone[8], and complementary statistics should emerge to overcome this limitation in interpretability.

Historically, the dominant approach for performing the full procedure of LME modelling + statistical inference has been the Frequentist LME (FLME) approach. However, different methods using a Bayesian LME (BLME) approach have been suggested[3,9]. As suggested in the editorial of Anna G.M. Temp et al.[10], Bayesian statistics can be used jointly with frequentist approaches to draw clinically relevant conclusions that can complement classical studies based uniquely on statistical significance.

In general words, the FLME approach is based on sampling distributions and on the Central Limit Theorem[11,12], and it treats the population parameters of interest as fixed values[11]. While in BLME, parameters are estimated from the population distribution, given the evidence provided by the observed data[11]. BLME is considered a more natural approach to answer a question, since it estimates the parameters of interest directly from the population distribution instead of estimating them from the sampling distribution[13]. The Bayesian approach treats the parameters of interest as random variables that can be described with probability distributions[11]. These posterior distributions can be compared directly without referring to statistical results of multiple tests. Overall, the differences in comparing frequentist vs Bayesian approaches in different fields have opened a debate in several fields[14–17].

Alzheimer's disease (AD) is clearly one of the research fields that will benefit from the development of longitudinal statistical methods. It is believed that AD is a slowly evolving process that likely begins years before the clinical symptoms are manifested[18,19]. Therefore, there is a strong interest in identifying subjects at high risk before the full clinical criteria for AD dementia are met[20,21], as well as in giving reliable prognosis at the subject's level. The existence of public available databases, such as the Alzheimer's disease neuroimaging initiative (ADNI) has facilitated the definition and validation of neuroimaging biomarkers for AD[22]. In this sense, the hippocampal volume (HV), derived from structural Magnetic Resonance Imaging (MRI) data, has become one of the most widely used biomarkers. Compared with healthy aging, HV is progressively affected in AD, being already reduced in patients with Mild Cognitive Impairment (MCI) due to AD and more strongly affected in advanced AD stages[23–25].

In the recent years, the longitudinal trajectories of some AD biomarkers using frequentist approaches have been widely described[1,9,26]. On the other hand, the attempts to incorporate Bayesian statistics have shown promising results[2,3,9]. Even if frequentist and Bayesian schools represent two different schools of thinking, they often complement to each other. In the present work we analysed longitudinal MRI data from the ADNI dataset, using both FLME and BLME approaches. We performed simulations of real-life datasets derived from a public big database to explore the robustness of the methods with limited sample sizes and missing data using both approaches. Our goal was to evaluate the pros and cons of these approaches in real-life scenarios. For this, we create (simulate) datasets that incorporate the common handicaps found in clinical studies, e.g., low number of participants, missing data points or unbalanced sets with the aim to provide recommendations for further studies as regards the use of frequentist and Bayesian approaches, whilst illustrating the limitations of both approaches and bringing attention to statistical significance and clinical relevance.

Materials and methods

Data. We used longitudinal brain MRI data (T1-weighted scans, combining 1.5 and 3.0 Tesla) from the ADNI database (adni.loni.usc.edu). The ADNI was launched in 2003 as a public–private partnership, led by Principal Investigator Michael W. Weiner, MD. Including participants from ADNI-1, ADNI-GO, ADNI-2 and ADNI-3. Scans had been previously preprocessed with the FreeSurfer Longitudinal stream[27], as explained elsewhere[28]. We focus our analyses on the HV, as it is a common AD biomarker and we include the total intracranial volume (ICV), as a known confound in neuroimaging studies. Therefore, we downloaded HV, ICV and demographics from the data server.

We included AD dementia and MCI patients, as well as Healthy control (HC) participants, as labelled by the ADNI consortium[21]. According to their clinical evolution, we further created the following groups:

1. *Stable HC (sHC)* subjects who were diagnosed as HC throughout the follow-up period.
2. *Converter HC (cHC)* subjects who were diagnosed as HC at baseline and progressed to MCI or AD dementia.
3. *Stable MCI (sMCI)* subjects who were diagnosed as MCI throughout the follow-up period.
4. *Converter MCI (cMCI)* subjects who were diagnosed as MCI at baseline and progressed to AD dementia.
5. *AD* subjects who were diagnosed as AD at baseline.

We initially selected subjects having at least two acquisitions and we created several datasets as starting points. Tables 1 and 2 provide descriptive statistics of our initially selected longitudinal samples.

The datasets used for the different analyses were:

1. *Dataset 1* consisted of all the available data from the 4 timepoints, as described in Tables 1 and 2 (N = 1250 subjects).
2. *Dataset 2* was a reduced version of *dataset 1* containing only sMCI and cMCI subjects (N = 680 subjects).

Variable	sHC	cHC	sMCI	cMCI	AD	p-value
N	273	78	361	319	219	
Baseline age (years)	74.3 ± 5.7	76.2 ± 5.1	72.9 ± 7.4	72.4 ± 7.5	74.7 ± 7.9	0.19
Sex (M/F)	142/131	40/38	212/149	184/135	123/96	0.41
APOE-e4 (nc/c)	207/66	52/26	203/158	121/198	64/155	< 0.0005

Table 1. Characteristics of the longitudinal ADNI sample used. Baseline age values are in mean ± standard deviation. M = male, F = female, nc = non-carriers, c = carriers. p-values indicate differences between group. We used ANOVA for baseline age, and Fisher's exact test for the other data.

Time point	sHC (N)	cHC (N)	sMCI (N)	cMCI (N)	AD (N)	Time from baseline (years)
Baseline	273	78	361	319	219	0.00
Year 0.5	243	71	326	274	187	0.51 ± 0.05
Year 1	234	70	294	275	173	1.01 ± 0.06
Year 2	206	61	233	240	97	2.02 ± 0.08

Table 2. Number of scans per time point by clinical group and time between scans. Time from baseline values are in mean ± standard deviation.

Variable	sHC	cHC	sMCI	cMCI	AD	p-value
N	172	53	187	186	72	
Baseline age (years)	74.2 ± 5.6	76.1 ± 5.4	72.0 ± 6.9	71.6 ± 7.6	74.2 ± 7.9	0.004
Sex (M/F)	96/76	24/29	104/83	107/79	40/32	0.62
APOE-ε4 (nc/c)	133/39	33/20	116/71	72/114	21/51	< 0.0005

Table 3. Characteristics of the balanced longitudinal ADNI sample used. Baseline age values are in mean ± standard deviation. M = male, F = female, nc = non-carriers, c=carriers. p-values indicate differences between group. We used ANOVA for baseline age, and Fisher's exact test for the other data.

3. *Dataset 3* was a homogeneous balanced database. We selected from *dataset 1*, subjects with 4 timepoints available. Demographics for this database are summarized in Table 3 (N = 670 subjects).
4. *Dataset 4* is a reduced version of *dataset 3* containing only sMCI and cMCI subjects (N = 373 subjects).

Implementation of LME models. As there is not a fixed rule for choosing the number of random effects in LME, we evaluated two different models. Both models included the Intercept term, or group-mean, as a random effect. For the first LME model, the fixed effects were: time from baseline, group, group-by-time interaction, baseline age, sex, APOE status, APOE-by-time interaction and ICV. For the second LME model, the slope (measured as time from baseline) was also included as a random effect and the rest of variables were left as fixed effects (see Supplementary Material for details). The selection of the variables to be included in the models was done mimicking the analysis performed by Bernal-Rusiel et al. and according to previous AD literature[29,30]. HV (the outcome variable of our model) and ICV (a fixed effect variable of the model) variables were standardized to zero mean and standard deviation of one, using Fisher's Z norm, to ensure that the estimated coefficients are all on the same scale and therefore the corresponding effect sizes are comparable.

Statistical inference. We first studied which of the two proposed LME models were more appropriate for our sample using the frequentist approach with ANOVA and the Akaike Information Criteria (AIC). We used an ANOVA with χ^2 test on the model parameters and coefficients estimated for both models and we assessed the significance with the likelihood ratio test[31].

We then used frequentist statistical inference to test some of the well-known research questions in the AD field. For that, we created a set of contrasts using F-tests and using Satterthwaite's method[32] to compute the degrees of freedom. The contrasts studied were:

1. Are there differences across the 5 groups? (i.e., ANOVA main effect).
2. Are there differences between sMCI and cMCI?
3. Are there differences between cMCI and AD?

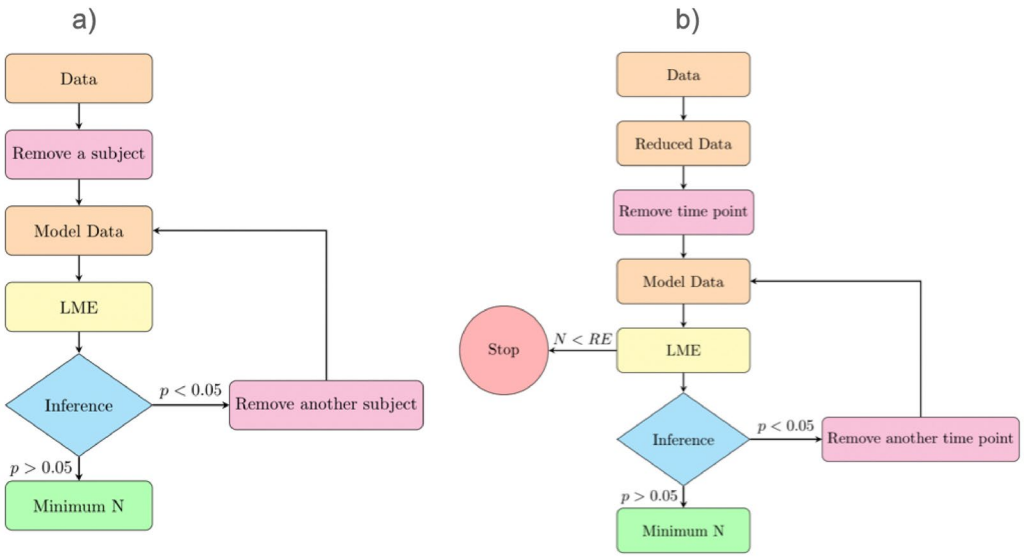

Figure 1. Simulations' scheme (**a**) Strategy for minimum N simulations. The initial data is dataset 1 or dataset 2. (**b**) Strategy of the simulation of missing time points. *RE*= random effects.

4. Are there differences between sHC and sMCI?
5. Are there differences between sHC and AD?
6. Are there differences between sHC and cMCI?
7. Are there differences between sHC and cHC?

We evaluated the LME model and tested these 7 contrasts in the datasets described previously (note that with dataset 2 or 4 we could only test contrast 1).

For the BLME approach, we also used the LME model with two random factors (the intercept and the slope). Posterior distribution measures regression parameters *ß* and contains all the information for statistical inference. We used the Credible Intervals (CrI) of this posterior distribution to study group differences. The CrI differ from the well-known Confidence Intervals (CI) in the fact that they are based in the uses of prior information and allow direct inferences about plausibility. Thus, CrI need the use of prior information to be estimated and can be interpreted as the probability in terms of plausibility[33]. We considered the four datasets and the same 7 contrasts described above.

All analyses were implemented in software R (https://www.r-project.org), version 3.6.2. For the LME model we used the *lme4* package[34] and the *rstan* package[35], so we combined R and Stan (https://mc-stan.org/) languages. The code for these analyses is available at https://github.com/Agnes2/LME-with-a-Bayesian-and-Frequentist-Approaches.git.

Simulation of real-life databases. Firstly, with the aim to provide a recommendation of the minimum N needed in these studies, we performed sequential simulations on the databases. We followed the scheme shown in Fig. 1a. We started from either dataset 1 (all groups) or dataset 2 (only MCI). We randomly selected one subject and we removed it (all its time points) from the dataset. Then we re-estimated the LME model, and we calculated the contrast of interest. This was repeated until the stopping criterion was met. At this point, we stored the last significant database, as a borderline significant dataset. Here, the stopping criterion was set at p-value > 0.05. This procedure was performed with dataset 1 (i.e., minimum N to differentiate across the 5 groups) and dataset *2* (i.e., minimum N to differentiate between sMCI and cMCI).

Further, with the aim to evaluate another typical situation in these studies, we also tested the effect of *missing timepoints*. We started from *dataset 3* (full balanced data) or *dataset 4* (MCI balanced data), and we proceeded as shown in Fig. 1b. First, we randomly selected one subject's time point of the sample and we removed it. We then estimated the FLME model, and we performed the corresponding statistical inference. We progressively removed time points from different subjects until the stopping criterion was met, and, as above, the last database was kept as a borderline significant database. The stopping criterion was set at p-value > 0.05. However, it should be mentioned that the FLME model cannot handle having more subjects' samples than random effects. Therefore, this restriction was added as an additional stopping criterion. The random effects were measured as $N \times 2$ subjects' samples, as we had a FLME model with randomly varying intercept and slope.

All the simulations were repeated over 500 iterations to account for the random selection of the subjects/timepoints to be removed at each step, leading to 500 *borderline significant databases*.

We applied BLME to the most compromised datasets found with FLME and we studied its behavior. Here, we performed a descriptive analysis in the borderline situations found with FLME. For that, we studied the obtained borderline datasets with the BLME model to estimate if they remained significant in the Bayesian framework and to evaluate the potential clinical interpretations that could be derived from them in terms of relevance.

Contrast	Dataset 1 F, p	Dataset 2 F, p	Dataset 3 F, p	Dataset 4 F, p
sMCI vs cMCI	39.2 5.6×10^{-10} *	36.1 3.2×10^{-9}*	31.8 2.5×10^{-8}*	24.2 1.3×10^{-6}*
All groups	22.8 4.1×10^{-18} *	–	15.1 8.5×10^{-12}*	–
AD vs cMCI	2.0 0.2	–	0.2 0.6	–
sHC vs sMCI	2.3 0.1	–	1.0 0.3	–
sHC vs AD	53.8 4.1×10^{-13}*	–	27.7 1.9×10^{-7}*	–
sHC vs cMCI	53.4 5.7×10^{-13}*	–	40.4 3.8×10^{-10}*	–
sHC vs cHC	2.3 0.1	–	2.7 0.1	–

Table 4. Summary of the null hypotheses tested and results of the statistical inference. *Indicates p-value < 0.05 (Bonferroni corrected).

Parameter	Interpretation	Estimate	95% CrI	
$ß_{11}$	cHC × time	−0.03	−0.06	0.01
$ß_{12}$	sMCI × time	−0.02	−0.04	0.01
$ß_{13}$	cMCI × time	−0.08	−0.11	−0.06*
$ß_{14}$	AD × time	−0.11	−0.13	−0.08*

Table 5. Estimation and 95% Credible Intervals (CrI) of the ßs of interest LME model fitted with a Bayesian approach. CrI borders are expressed as the 2.5% and 97.5% percentiles. *Indicates that the effect is significant (i.e., CrI does not contain zero).

Results

Statistics on ADNI longitudinal databases. Of the two possible LME models to fit our data—one with the intercept as a random effect and another with intercept and slope as random effects—we found that the second one performed better for explaining our data. This was verified by the results of the ANOVA (p-value <<< 0.001) and by comparing their AIC values (1546.2 vs 1411.7). Therefore, all further analyses were performed with this model. To obtain comparable results, we also used intercept and slope as random effects in the BLME model.

We applied the FLME model followed by a set of F-tests to evaluate the contrasts of interest in the four databases described above. Results are shown in Table 4, and they reproduce previous reports on the field (as those presented in Ref.[1]). Mainly, we found significant differences in HV (p-value < 0.05) between all the five clinical groups, between sMCI and cMCI, between sHC and AD and between sHC and cMCI for the four initial datasets configurations. All these differences remained significant after correcting for multiple comparisons using Bonferroni (n = 7 tests, p-value < 0.05/7).

After fitting the BLME model, we obtained the joint posterior probability of the parameters. Here, we were interested in the posterior probability distribution for the ßs, and we used the interval from 2.5th to 97.5th percentiles to obtain the 95% CrI[36]. We focused on the ßs that represented change over time for the different groups (with sHC being the reference group). Results for dataset 1 are shown in Table 5. We found that the effect of time was significant (i.e., the 95% CrIs did not contain zero) for cMCI and for AD, while it was not significant for cHC and sMCI. When comparing groups, which not contain the reference group, we considered that there were differences when the corresponding CrI did not overlap. The contrasts with significant differences are the same as those depicted by the FLME approach.

Finding compromised datasets with FLME. *Minimum N simulations.* By evaluating the 500 databases obtained from the procedure described in Fig. 1a and starting from dataset 1, we found that the minimum N needed to differentiate the five clinical groups (with p-value < 0.05) using the HV measure was N = 147 ± 73 overall. As the removal process followed a random order, the number of subjects within each group was not fixed by the algorithm. The group distribution resulting from the 500 databases is shown in Fig. 2a.

Similarly, with the same procedure and starting from database 2, we found that the minimum N needed to differentiate cMCI and sMCI using HV measures was N = 115 ± 64 overall. The distribution of the groups within the 500 obtained databases is shown in Fig. 2b.

Missing points simulations. For these simulations, in both cases (starting from *database 3* and *database 4*), we rapidly encountered that the limitation of number of samples < number of random effects. Thus, evidencing the low robustness of FLME approaches with highly unbalanced data.

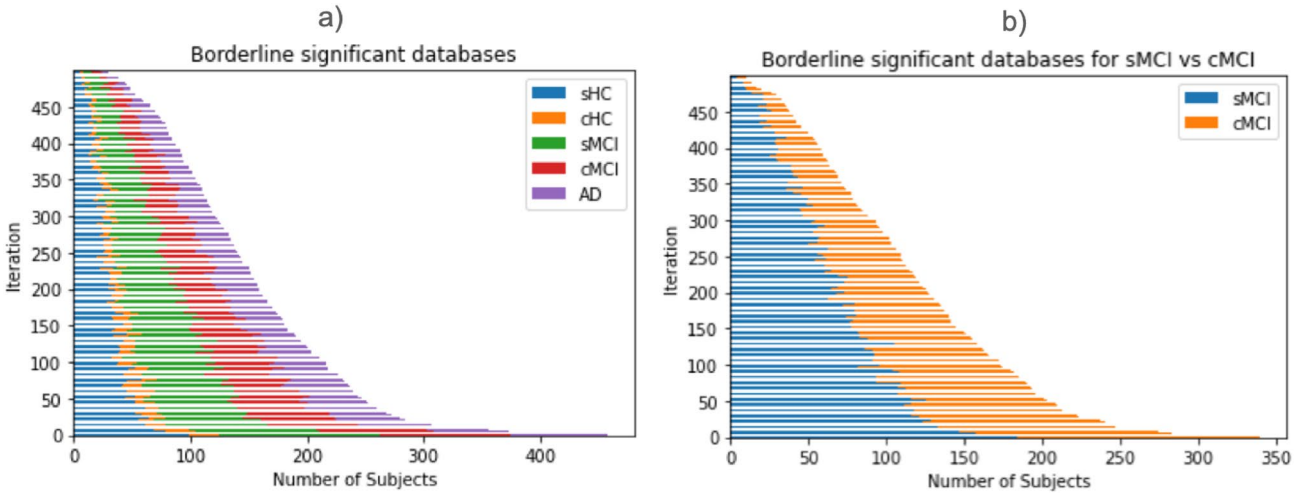

Figure 2. Distribution of subjects within each group for all the obtained databases (**a**) minimum N simulation across five clinical groups (**b**) minimum N simulation across MCI group.

By analysing the *database 3* (initial N = 670 with 4 time points per subject), with the process described in Fig. 1b, the simulations stopped at N = 612 ± 9 subjects (with different number of time points per subject), except from 3 iterations that did not converge into a failing database considered as outliers. At the moment that it was impossible to estimate the FLME model we had a mean of 2 missing time points per subject.

Similarly, with the same procedure and starting from *database 4* (initial N = 373 with 4 time points per subject) we found that the simulations stopped at N = 341 ± 7 except from 45 databases that did not stop. At the point that it was impossible to estimate the FLME model we had again a mean of 2 missing time point per subject.

Evaluating compromised datasets with BLME. *Minimum N simulations.* We studied the behaviour of BLME approach on different datasets obtained from the frequentist simulations of the minimum N. We first picked 10 different databases depicting differences across the 5 clinical groups, but that were at the limit for significance. These were randomly selected from the 500 iterations of the FLME experiments (the full characteristics of these databases are described in Supplementary Material). When studied with a BLME approach, 9 of them showed differences across the 5 groups. Figure 3a represents two of the datasets obtained in the simulation of the minimum N. Then, we selected 10 databases obtained from the simulations with dataset 2 (i.e., minimum N to find differences between sMCI and cMC). In this case, only 2 datasets remained significant when studied with the BLME approach. Figure 3b shows an example of the datasets obtained with the simulation of the minimum N.

Missing points simulations. To estimate the FLME model with a frequentist approach we encountered a practical limitation inherent to the model: the need to have more samples than random effects. Here, we selected 10 databases, from the FLME simulations, at the point that they no longer met the requirement. Thus, with these databases it was impossible to estimate a FLME model. The full characteristics of these databases are described in Supplementary Material. We studied with a BLME model these 10 databases. We found that the model can be estimated, and that all the databases depicted differences across the 5 groups (see Supplementary Material). For the 10 stopping databases created from the simulations with *dataset 4* we found similar results (see Supplementary Material), we could estimate the model and present differences for sMCI vs cMCI. Figure 3c,d represents Dataset 3 and 4 with one example of the datasets obtained after the missing points simulations for each situation.

Discussion

In this study, we explored large longitudinal neuroimage datasets obtained from ADNI to study trajectories of hippocampal volume change in AD. For that, we created LME models under the frequentist and the Bayesian frameworks. We found that both approaches have similar behavior in finding differences with the entire database. In the minimum N simulations, the Bayesian approach was slightly stricter to significance when reducing data size. In addition, our results indicated that the Bayesian approach is more robust to unbalanced and sparse databases with different number of measurements across subjects.

Firstly, our investigation supports the use of LME approaches to model longitudinal data. The results of our null hypotheses testing agreed with those reported previously in AD for the hippocampus[1,2]. Additionally, we provide evidence of the utility of these apparently more complex analyses to study compromised datasets with different time points for across subjects.

The frequentist approach allowed us to implement a method for testing the relationship between the sample characteristics (size and missing points) and the expected group differences. Even considering that the statistical threshold (here $p < 0.05$) may be rather arbitrary (see[37,38]), it is important to note that this was chosen as a controlled systematic approach to study the behavior of the databases when removing subjects, with the ultimate

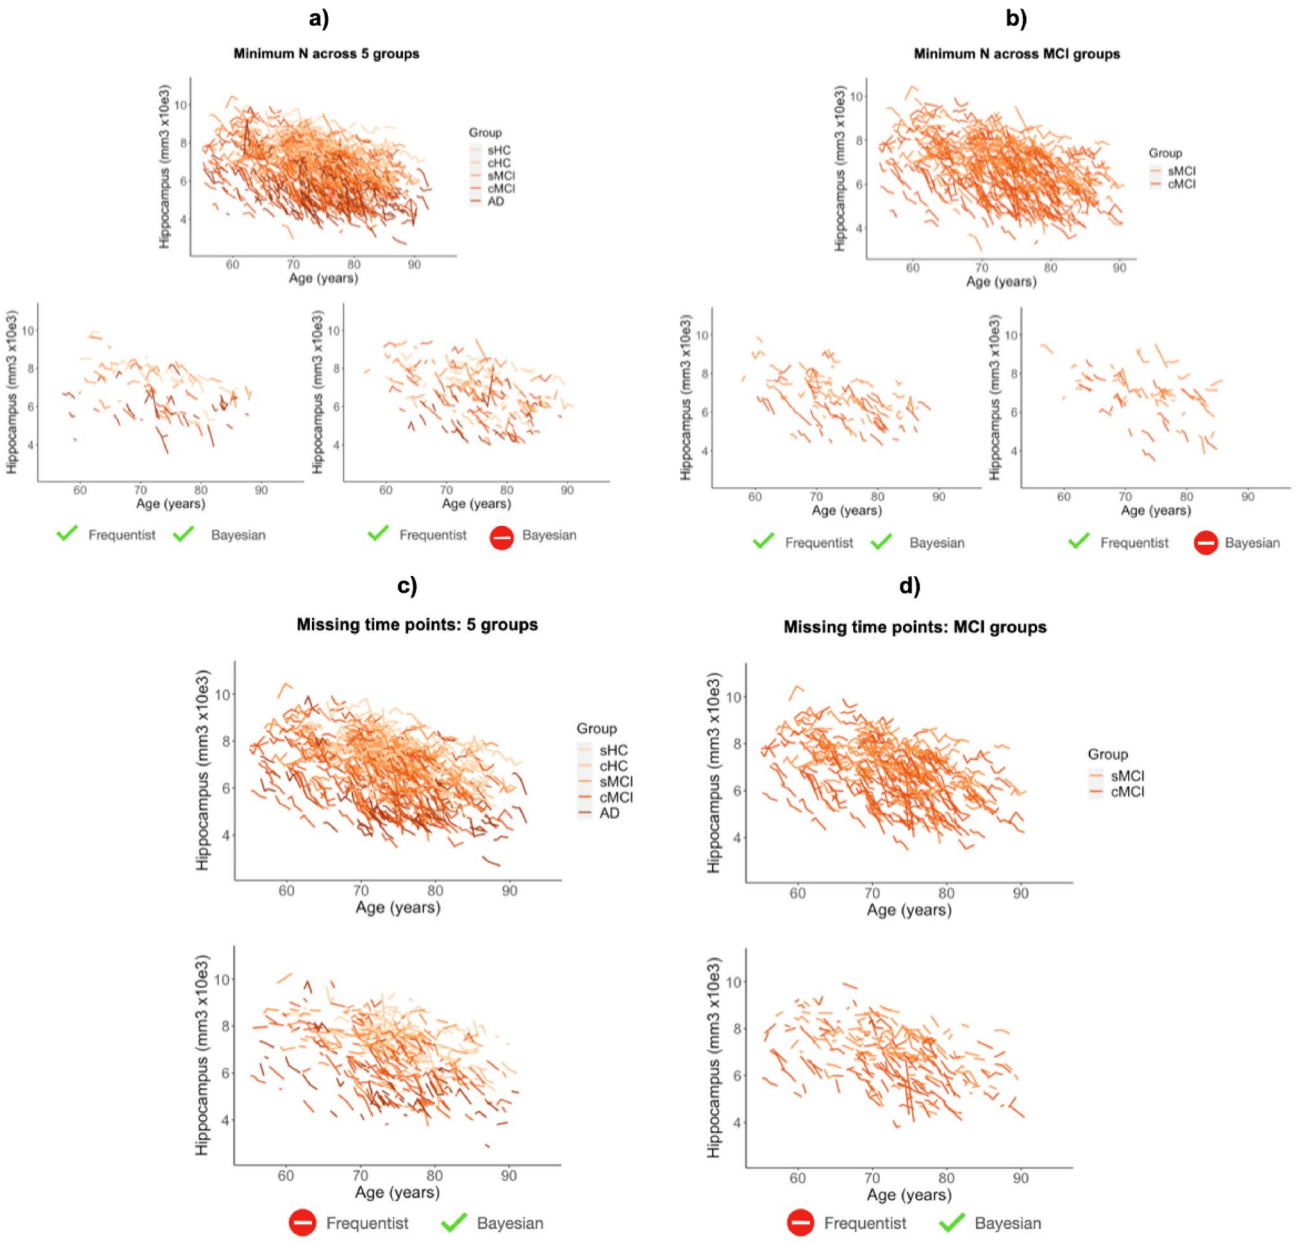

Figure 3. Hippocampus volume versus age. Top plots (**a,b**) represent dataset 1 (**a**) and 2 (**b**) with initial N. Bottom plots (**a,b**) represent four different databases obtained after the simulation of minimum N, resulting significant for frequentist and Bayesian approaches and only for frequentist approach. Top plots (**c,d**) represent dataset 3 (**c**) and 4 (**d**). Bottom plots (**c,d**) represent different databases obtained after the simulation of missing time points, being only estimable for Bayesian approach.

goal to evaluate the behavior of both approaches in different scenarios. To our knowledge, there are no previous studies addressing similar questions with neuroimaging data.

In a further step, we aimed to explore the utility of Bayesian statistics combined with LME modelling. It has been suggested that Bayesian approaches could complement the findings obtained with frequentist analyses, as they provide a more interpretable framework. Bayesian models are based on the direct estimation from the population distribution represented by the posterior distribution, instead of estimating from the hypothetical sampling distribution as it happens in the frequentist approach[13]. In this context, our BLME model can be interpreted in a probabilistic way and may offer a more direct interpretation in clinical settings than FLME[13,14]. Contrarily, the FLME approach does not accept probabilistic interpretation although many researchers use them to interpret their results[39]. As we observed when testing large databases, the two approximations of LME model often led to similar conclusions. Indeed, our results in terms of statistical significance support previous research on the role of HV as a biomarker for AD, being highly significant across groups and between converters and non-converters. However, when repeating all comparisons with BLME, we aimed to add clinical relevance to the above significance statement. This was more evidenced when studying compromised datasets. That is, by using

posterior distributions, longitudinal analyses can be better adapted to real-life datasets with clinical relevance. Overall, we emphasize the need of knowing the characteristics of the sample to be able to infer the correct interpretation of the results. For example, it is known that with a non-informative prior, Bayesian approaches tend to mimic frequentist results from the numerical point of view[11]. Little by little more studies use Bayesian approaches in the context of neuroimaging and dementia. In a similar context, Cespedes et al. demonstrated that the use of BLME can be useful for estimating atrophy rates in The Australian Imaging, Biomarker & Lifestyle Flagship Study of Ageing cohort (AIBL) (https://aibl.csiro.au). Bayesian statistics were used in the ADNI database in a latent time joint mixed-effects model to provide a continuous alternative to clinical diagnosis[40]. And, in a more complex approach, the authors implemented a multi-task Bayesian learning algorithm on the ADNI database to model trajectories of biomarkers at the individual level[9]. Although these studies clearly differ from ours, they support the use of Bayesian approaches in clinical contexts. In addition, Bayesian statistics appear as a good framework to solve clinically relevant questions that cannot be addressed with frequentist approaches. For example, the absence of effects[10].

We calculated the minimum sample size that led to significant group differences with FLME, and we obtained values (overall values for the studied groups) of 147 and 115 for all groups and for MCI conversion to dementia respectively. It should be mentioned that the main goal of this study was not sample size estimation and thus, these values are rather indicative, in the sense that they are restricted to the research questions and the measure used in this study. However, we believe that they can be of interest in the context of clinical trials. In a study with frontotemporal dementia, Staffaroni et al. calculated the estimated sample size using bootstrapping techniques for different cognitive and imaging measures and they obtained values from < 100 to > 500 depending on the measure or combination of measures chosen[41].

By studying highly compromised datasets (those at the border classical frequentist significance at p-value < 0.05), we were able to compare the two approaches. Notably, not all the borderline databases identified with FLME (i.e., p-value nearly 0.05) remained significant with the BLME approach. This may be due to the fact that accurate modelling of the variances in the Bayesian framework led to more restrictive statistics. It should be mentioned that the ADNI database is quite heterogeneous as do not have the same time point for each subject and that our analyses did not control for some external covariates such as different centers and scanners that might add variability.

In addition, it should be noted that our strategy for comparing approaches was based on selecting the datasets with FLME followed by the evaluation of significance with BLME. This strategy allowed us to obtain important insights as regards significance and interpretability for longitudinal modelling. However, the above conclusions are restricted to this and should not be generalized to any dataset.

The other group of simulations that we implemented was related to databases with missing points. In this sense, an important drawback for FLME modelling is the need of having more subjects' samples than random effects for the model to be estimated. In practice, this was the main reason for stopping in these simulations. Instead, the Bayesian approach allowed estimating the LME model even with high number of missing points in the database. More specifically, our results show that the BLME model is feasible in a 4-timepoint database that has approximately 2 missing values for each subject, suggesting that the Bayesian framework should be chosen for longitudinal modelling in sparse databases. Other studies have demonstrated that Bayesian statistics overcome some of the limitations of classical statistical inference in non-homogeneous databases[3].

Our study has several limitations. First, one difficulty of using the Bayesian approach is its complexity in computing posterior distributions used to estimate the CrI. This has historically imposed an important barrier[13]. Although software solutions have improved in the last years, the frequentist approach is still computationally easier. Further studies should explore the utilization of Markov Chain Monte Carlo approaches to overcome this limitation. Due to this high computational cost of the BLME, the implementation of a method for testing sequential data removal with BLME was out of reach of this study. Second, the current study is based on the HV measure, and the conclusions are specific for this. To be able to generalize our conclusions to broader contexts, other MRI biomarkers for AD, and eventually other databases, should be studied. Third, in the ADNI dataset, there are acquisition differences (i.e., different scanners) which were not included in the analyses. This could have an impact on the HV measurements. Finally, the clinical diagnosis available in the ADNI dataset does not systematically include CSF validation, which, according to the latest MCI diagnostic criteria[42,43], may result in some subjects wrongly labelled as HC or MCI. Other sources of misclassification (or confusing diagnosis) refer to the fact that other pathologies may coexist in subjects diagnosed with AD and that different AD subtypes show different biomarker trajectories. Our results did not account for misdiagnosis nor subgrouping, as ground truth labels were not available. We believe that further studies, possibly using unsupervised machine learning, could account for these factors.

Data availability

Publicly available datasets were analyzed in this study. This data can be found at: adni.loni.usc.edu.

Code availability

Analyses code is available at https://github.com/Agnes2/LME-with-a-Bayesian-and-Frequentist-Approaches.git.

2 Supplementary Methods

Exact expression for the models of the LME models of the Section 2.2

The model with only intercept as random effect can be written as follows, where *i* indicates the subject and *j* indicates the time point:

$$Y_{ij} = \beta_1 + \beta_2 cHC_i + \beta_3 time_{ij} + \beta_4 sMCI_i + \beta_5 cMCI_i + \beta_6 AD_i + \beta_7 APOE4_i + \beta_8 SEX_i$$

$$+\beta_9 AGE_i + \beta_{10} ICV_i + \beta_{11} cHC_i time_{ij} + \beta_{12} sMCI_i time_{ij} + \beta_{13} cMCI_i time_{ij} + \beta_{14} AD_i time_{ij}$$

$$+\beta_{15} APOE4_i time_{ij} + b_{1i} + e_{ij}$$

While the model with intercept and slope as random effects can be written as:

$$Y_{ij} = \beta_1 + \beta_2 cHC_i + \beta_3 time_{ij} + \beta_4 sMCI_i + \beta_5 cMCI_i + \beta_6 AD_i + \beta_7 APOE4_i + \beta_8 SEX_i$$

$$+\beta_9 AGE_i + \beta_{10} ICV_i + \beta_{11} cHC_i time_{ij} + \beta_{12} sMCI_i time_{ij} + \beta_{13} cMCI_i time_{ij} + \beta_{14} AD_i time_{ij}$$

$$+\beta_{15} APOE4_i time_{ij} + b_{1i} + b_{2i} time_{ij} + e_{ij}$$

With the following variables:

Y_{ij}: The variable to predicted. Here, HV.

$time_{ij}$: time from baseline (in years).

cHC_i=1: if subject is cHC and 0 otherwise.

$sMCI_i$=1: if subject is sMCI and 0 otherwise.

$cMCI_i$=1: if subject is cMCI and 0 otherwise.

AD_i=1: if subject is AD and 0 otherwise.

$APOE4_i$=1: if subject has at least one e4 allele and 0 otherwise.

SEX_i=1: if subject female and 0 otherwise.

AGE_i: age at baseline (in years).

ICV_i: total intracranial volume (in litres).

b_{1i}: random effect for the intercept term.

b_{2i}: random effect for the slope term.

e_{ij}: error term

ABSTRACT

Background and objectives: Alzheimer's disease (AD) and frontotemporal dementia (FTD) show different patterns of cortical thickness (CTh) loss compared with healthy controls (HC), even though there is relevant heterogeneity between individuals suffering from each of these diseases. Thus, we developed CTh models to study individual variability in AD, FTD, and HC.

Methods: We used the baseline CTh measures of 374 participants obtained from the structural MRI processed with FreeSurfer. A total of 169 AD patients (63 ± 9 years, 65 men), 88 FTD patients (64 ± 9 years, 43 men), and 122 HC (62 ± 10 years, 47 men) were studied. We fitted region-wise temporal models of CTh using Support Vector Regression. Then, we studied associations of individual deviations from the model with cerebrospinal fluid levels of neurofilament light chain (NfL) and 14-3-3 protein and Mini-Mental State Examination (MMSE). Furthermore, we used real longitudinal data from 144 participants to test model predictivity.

Results: We defined CTh spatiotemporal models for each group with a reliable fit. Individual deviation correlated with MMSE for AD and with NfL for FTD. AD patients with higher deviations from the trend presented higher MMSE values. In FTD, lower NfL levels were associated with higher deviations from the CTh prediction. For AD and HC, we could predict longitudinal visits with the presented model trained with baseline data. For FTD, the longitudinal visits had more variability.

Conclusion: We highlight the value of CTh models for studying AD and FTD longitudinal changes and variability and their relationships with cognitive features and biomarkers.

Keywords

Alzheimer's disease, frontotemporal dementia, magnetic resonance imaging, cortical thickness, predictive modeling

1. INTRODUCTION

During the last two decades, the study of several biomarkers, including neuroimaging, has substantially improved the diagnosis of neurodegenerative dementias. However, there's still a need for reliable biomarkers to track disease, evaluate the effect of experimental drugs, or provide an accurate prognosis. Both Alzheimer's disease (AD) and frontotemporal dementia (FTD) are characterized by prototypical clinical features and patterns of progressive brain atrophy that constitute the disease's fingerprint or signature. However, both diseases show relatively high individual heterogeneity in presentation and progression rate. The study of this variability is relevant to better understanding these diseases' pathogenesis and predicting disease progression and potentially the effect of treatments [1]. Previous studies also suggest that the age of onset might influence the longitudinal evolution of AD patients [2, 3], emphasizing the need to model age and time from symptoms onset.

Quantitative neuroimaging studies with Magnetic Resonance Imaging (MRI) have been widely used to detect brain changes across these neurodegenerative disorders, using measures such as the cortical thickness (CTh) [4–6], but mostly in research studies. Cerebrospinal fluid (CSF) biomarkers, such as the amyloid-beta protein 42 (Aβ42), the total tau (t-tau), and phosphorylated tau (p-tau) have been included in the current criteria for AD diagnosis [7, 8]. Other CSF-biomarkers, such as neurofilament light chain (NfL) levels, a marker of neuroaxonal damage, and 14-3-3 protein levels, a marker of synaptic-neuronal loss, have been both proposed as nonspecific neurodegeneration markers [9–12].

Modeling approaches that account for time are of paramount importance to understanding disease progression and comparing brain status across subjects at different disease stages [13–16]. Using structural MRI, some authors described CTh loss with time, providing valuable information on the characterization of disease trajectories and validation of prognostic biomarkers [17, 18].

We hypothesized that dementia is characterized by high variability in atrophy patterns reflecting clinical and biological differences across subjects. In this prospective study with 379 subjects, we aimed to develop CTh models for each diagnosis group (AD, FTD, and healthy controls (HC)), considering time from disease onset. We further aimed to study individual variability with respect to the model and evaluate the effect of the time from disease onset, cognition, and biochemical markers in the individual

deviations from the model. Finally, we aimed to test these pseudo-longitudinal models in predicting the real longitudinal CTh evolution of a subsample of subjects.

2. MATERIALS AND METHODS

2.1. Participants

The prospective study includes 379 participants recruited from the Alzheimer's disease and other cognitive disorders group of the Hospital Clínic de Barcelona (HCB), Barcelona, Spain. The study was approved by the HCB Ethics Committee (HCB 2019/0105), complied with the Declaration of Helsinki, and all participants gave written informed consent. All participants underwent a complete clinical and cognitive evaluation [3, 19] and at least one 3T high-resolution structural MRI scan. A subset of these participants had novel CSF measures. A total of 309 participants had available CSF-NfL levels, and 160 participants had available CSF-14-3-3 measures. Additionally, a subset of 144 subjects underwent a second MRI scan 2 years after the baseline and 58 subjects with 4 years after the baseline scan. Participants with a history of stroke, traumatic brain injury, major psychiatric disorder, or alcohol abuse were excluded. Participants were classified into three groups:

- AD: participants meeting criteria for MCI or mild dementia due to AD [7, 8] supported by CSF-biomarkers profile suggesting underlying AD neuropathology according to National Institute on Aging/Alzheimer's Association Research Framework 2018 [20].
- FTD: patients who met diagnostic criteria for either behavioral variant frontotemporal dementia (bvFTD) or FTD-related primary progressive aphasia (PPA) phenotypes, including Semantic Variant Primary Progressive Aphasia (svPPA) and Nonfluent Variant Primary Progressive Aphasia (nfvPPA) [21, 22]. All FTD patients included here showed a CSF profile not suggestive of AD.
- HC: healthy adults having cognitive performance within the normative range (cutoff 1.5 SD from the normative mean).

2.2 CSF-biomarkers

Commercially available single-analyte enzyme-linked immunosorbent assay (ELISA) kits were used to determine levels of CSF-NfL (IBL International, Hamburg, Germany) and 14-3-3 (CircuLex, MBL International Corporation, Woburn, MA) at the Alzheimer's disease and other cognitive disorders group laboratory, Barcelona, Spain.

2.3 MRI acquisition

A high-resolution 3D structural dataset (T1-weighted, MP-RAGE, repetition time = 2.300 ms, echo time = 2.98 ms, 240 slices, field-of-view = 256 mm, voxel size = 1 × 1 × 1 mm) was acquired for everyone at each time point in a 3T Magnetom Trio Tim scanner (Siemens Medical Systems, Germany) upgraded to a 3T Prisma scanner (Siemens Medical Systems, Germany) during the study.

2.4 MRI processing

We used FreeSurfer version 6.0 (http://surfer.nmr.mgh.harvard.edu.sire.ub.edu/) to perform cortical reconstruction of the T1-weighted acquisitions [23–25]. FreeSurfer allowed us to generate automated CTh maps for the left and the right hemispheres and to obtain summary measures within regions. We used the 68 cortical parcellations derived from the Desikan atlas available in FreeSurfer [26].

2.5 CTh models

We used the CTh values at baseline to generate three CTh models over time using Support Vector Regression (SVR). For the time variable, we used the chronological age of the subjects for HC subjects and years of disease duration (YDD) for patients. YDD were calculated as the difference between the age at MRI acquisition and the age of disease onset for each patient. All groups were modeled separately. To train the three CTh models, we used the following strategy: the HC model was trained with HC participants, the AD model was trained with AD patients, and the FTD model was trained with FTD patients. We introduced regional measures of both hemispheres leading to a total of 68 CTh values per subject together with time (chronological age or YDD) to train the SVR model. The overall performance of each model was assessed using the root-mean-square error (RMSE) for each CTh region (i.e., the error

between estimated and real values), averaged across individuals. During training, the following SVR hyperparameters were introduced with a Grid Search, and we used a cross-validation of 5 folds with the train set (all the cross-sectional data). Models were implemented in Python version 3.10.6 (www.python.org) with the scikit-learn library [27].

2.6. Correlation with CSF-biomarkers and cognition

We calculated the individual residuals of the model for each region and disease (Figure 1A). We obtained deviations from the HC-derived model for each patient, and we computed the correlation between these residuals and Mini-Mental State Examination (MMSE) scores and YDD. Then, we estimated the deviations from its own disease model and computed the correlation between the obtained residuals and available CSF-biomarkers levels (NfL and 14-3-3) and MMSE scores. The FTD group was first studied as a whole and further divided into subgroups (bvFTD, svPPA, and nfvPPA). A p-value<0.05 was set as the threshold for significance in the correlations after applying the correction for multiple comparisons for the number of regions with Benjamini-Hochberg for all the analyses. Correlations were implemented in R language, version 4.2.1 (https://www.r-project.org).

2.7 Prediction of longitudinal changes in CTh maps

The longitudinal data were used as unseen test samples to obtain individual predictions using the group-specific CTh models. Then, we calculated the mean absolute error (MAE) between predicted and real measures for each region (Figure 1B). We also studied the different subgroups of FTD patients (bvFTD, nfvPPA, and svPPA). These comparisons were also implemented in R version 4.2.1.

3. RESULTS

3.1. Sample demographics

Of the 379 subjects included in the analyses, 169 were AD patients (n=29, 2 years follow-up), 88 were FTD (n=27, with 2 years follow-up, and n=9, with 4 years follow-up), and 122 were HC (n=88, with 2 years follow-up, and n=49, with 4 years follow-up). The FTD group included 47 bvFTD patients (n=11, with 2 years follow-up, and n=4, with 4 years follow-up), 22 svPPA patients (n=9, with 2 years follow-

up, and n=3, with 4 years follow-up), 17 nfvPPA patients (n=6, 2 years follow-up), and 2 unspecified PPA patients (n=1, 2 years follow-up). Of the 309 subjects with available NfL levels, 144 were AD patients, 63 were FTD patients, and 102 were healthy controls. For the 14-3-3 samples, we had 66 AD patients, 54 FTD patients, and 40 healthy controls with available data for our analysis. Figure 2 shows a schema of the samples available for each analysis. Demographic information and group statistics are shown in Table 1 and in Supplementary Material. In summary, as expected, CSF-biomarkers levels and MMSE scores showed significant differences between groups (corrected p-value<0.05). Notably, the time between scans was modeled inside the models to control the potential differences between individuals.

3.2. CTh models with time and correlations with disease duration and cognition

We obtained a CTh model for HC with chronological age. The mean RMSE of the model was 0.024. Then, we obtained individual deviations for HC, AD, and FTD subjects from this HC model using the residuals (Figure 3A). HC subjects showed values around zero, meaning that the observed and estimated values are closer for most subjects, indicating a good fit. We obtained high residual values (absolute values between 0.01 and 0.77) for the AD and FTD, indicating high deviations from the HC-defined model (Figure 3A). The negative residuals indicate that the real CTh values of AD and FTD subjects were lower than those estimated by the HC model. In AD, higher deviations from the HC model were only associated with higher YDD in the regions: right bankssts, right transverse temporal, right lateral orbitofrontal, and right frontal pole and with MMSE in temporal and parietal regions (corrected p-value<0.05, Figure 3B). No significant correlations were identified in FTD.

3.3. CTh models with years of disease duration and correlations with CSF-biomarkers and cognition

We estimated CTh models for AD and FTD using YDD in the temporal axis. We obtained estimations of CTh in a span from 0 to 9 YDD, and we calculated the individual variations between each individual point and the estimation. The maps of variability across regions and time are shown in Figure 4. The mean individual deviation from the model (RMSE values) for these models was: 0.08 for FTD and 0.04 for AD. We also calculated the mean values by YDD subgroups (see Supplementary Material). We studied the correlation between individual residuals from their disease model and individual CSF-NfL and CSF-14-3-3 levels and MMSE scores. In AD, the residuals of the right precentral and right entorhinal

regions had a significant negative correlation with NfL levels (corrected p-value<0.05, Figure 5A). The residuals of the temporal and parietal lobes positively correlated with MMSE scores, so participants with higher residual values correspond to participants with higher MMSE scores (corrected p-value<0.05, Figure 5A). We did not find any correlation between 14-3-3 levels and the residuals for AD patients. In FTD, we found significant negative correlations (p-value<0.05, corrected) between NfL values and the residuals of the model in regions of the frontal, temporal, and parietal lobes (Figure 5B). For 14-3-3 levels and MMSE scores, we did not find significant results. When we studied the different FTD variants, we found a negative correlation between NfL and individual residuals for bvFTD in frontal, temporal, and parietal regions (corrected p-value<0.05, see Supplementary Material). For the other variants (svPPA and nfvPPA), we did not find any correlation with NfL. However, high caudal middle frontal right region deviations were associated with high MMSE scores for the nfvPPA patients (corrected p-value<0.05, see Supplementary Material). As before, 14-3-3 levels showed no significant correlation for bvFTD, svPPA, or nfvPPA. These correlations remained significant when age was included as a covariate.

3.4. CTh prediction of follow-up visits

Finally, we explored whether the predictive CTh models trained with the baseline data could be used to predict future real CTh values. For that, we calculated the mean absolute error (MAE) values contrasting the real values (Figure 6) at each longitudinal timepoint with their predicted disease model values. Also, we estimated the MAE (computed internally within the model data) for the baseline visit to use as a reference. For HC and AD (Figure 6A), the predictive model trained with baseline data allows the prediction of future visits with low error, as the mean MAE were 0.12 and 0.15, respectively, for all the timepoints. For FTD (Figure 6A), the 2 years follow-up visit could be predicted reasonably well (mean MAE 0.20 at baseline and 0.22 at 2 years), however, the model could not present an optimal prediction for the 4 years follow-up visit (mean MAE 0.25). We repeated the analysis with FTD data divided into subgroups (Figure 6B), (bvFTD, nfvPPA, and svPPA). Despite the limited sample size, we found results like the whole FTD group for bvFTD and svPPA. For the nfvPPA patients (only data at 2 years follow-up), we find the worst results in terms of predictive accuracy. In the Supplementary Material, we specify the mean MAE for each group and subgroup.

4. DISCUSSION

In this work, we implemented group-specific models of whole brain CTh according to chronological age for HC and YDD for AD and FTD patients using SVR. We modeled CTh changes with time, and we demonstrated these models' capability to identify individual variations as deviations from the norm. We studied individual deviations from the model defined for HC and from the disease-specific models. In AD, individual deviations from the HC-defined model correlated with YDD and MMSE scores. Using the disease-specific models, we found a significant inverse correlation between CSF-NfL levels and the deviation from the model in most of the brain regions for FTD patients, providing additional evidence of the relationship between imaging and fluid biomarkers in FTD. Furthermore, we found a positive correlation for AD between the MMSE scores and the deviation from the model in multiple regions. Finally, using real longitudinal data, we performed an exploratory study to evaluate the ability of the models described above to obtain individual predictions of future CTh values.

In healthy subjects, our model estimated whole-brain CTh using the chronological age of the subjects with residual values near zero, indicating a good fit. Several studies and multi-centric initiatives have recently focused on studying normative models with age in healthy samples [15]. Even if our healthy sample is limited compared to these studies, our results align with what has been described. In addition, we offer the applicability of such models with longitudinal data with satisfactory results. Furthermore, as deviations from normality have been widely used to assess disease severity and cognitive variability in youth [28] and in psychiatric disorders [29], we study if AD and FTD patients could be described with the previous HC model. As expected, individual AD and FTD CTh data diverged from the model defined with HC subjects. In AD, this divergence was significantly correlated with YDD and MMSE but not in FTD, suggesting that both time and general cognition impact more consistently in CTh changes compared to HC in AD. In AD, the regions of the temporal, parietal, and occipital lobes were the ones with the highest deviations from the HC model. These regions have been reported to be the most affected in patients with AD [30–33]. Therefore, our study can identify meaningful atrophy patterns using estimation models. On the other hand, the temporal and frontal lobes were the ones with the highest deviations for the FTD patients compared to the HC trend. In addition, temporal regions presented higher deviation than the AD group, depicting higher structural alterations in FTD [11, 32, 34, 35].

Given that models derived from the HC group that used chronological age showed high variability for these groups, we expected that modeling disease duration could better capture these variations. In this sense, we described CTh models in AD and FTD using YDD instead of the chronological age. Even though both AD and FTD individual values evidence the existence of variability within these diseases. These results complement other research highlighting these models to assess heterogeneity in neurodegenerative disorders [1, 36, 37].

We found that the individual AD deviations from the AD CTh model in the right precentral and right entorhinal inversely correlated with the NfL levels. At the regional level, the correlations between MMSE scores and the deviations from the model in AD were in the temporal and parietal lobes. In AD, MMSE has been associated with CTh [4, 33, 38]. In our case, the AD patients who deviated more from the model trend had high MMSE scores. Previous studies such as Valtteri et al. 2010 [38] showed that less CTh in frontal and temporal lobes is associated with lower MMSE scores in the AD group, which coincides with our regions and the direction of the correlation. Even if we study variability and not direct CTh measures, the regions that appear significant in the correlation analysis have high coincidence with the AD cortical pattern, which includes the temporal and parietal lobes appear [30, 31, 33, 34].

The deviations of the FTD patients from their own model presented correlations with CSF-NfL levels in the frontal, temporal, and parietal lobes. The frontal and temporal areas are known to be the most affected in patients with FTD compared to HC [32, 34, 39]. In FTD, NfL levels have been suggested as a maker of the disease severity [40, 41]. We found that higher levels of NfL corresponded to lower residual values. Thus, patients with CTh patterns that adjusted well to the model had higher CSF-NfL levels, suggesting that the model captures the trend of neurodegeneration. Instead, lower NfL levels could correspond to patients that move further away from the FTD model, as has been described for slowly progressive FTD or non-progressors FTD [42]. Indeed, when studying the different FTD variants, we found that the main pattern was mainly driven by bvFTD, as other variants, such as PPA, showed much higher deviation. In addition, the fact that the parietal lobule emerged, which has not been reported previously, could be due to the high presence of bvFTD patients in the FTD sample. At the same time, the individual deviations in PPA patients did not present any significant correlation with NfL, suggesting that the heterogeneity in

these patients' CTh pattern is not related to CSF-NfL levels. These results might provide additional support to the use of NfL levels as a marker of neurodegeneration and disease severity in FTD, paving the way for its future use as an outcome measure for clinical practice. In addition, the inexistent correlation with MMSE scores in FTD patients could be due to the fact that MMSE is not a sensitive cognitive measure in these patients, contrary to AD patients.

At the longitudinal level, we explored the application of these predictive models, trained at a cross-sectional level, to predict CTh patterns for future visits. We used the longitudinal data to know if the pseudo-longitudinal models developed with baseline data could predict the CTh values of future visits of these patients. We compared the predicted values of the longitudinal data with the real values of those visits. For healthy subjects and AD, we found that the model could predict well the CTh values at future visits. For FTD patients, the variability observed at baseline was reproduced for the longitudinal data and increased at each visit. Then, we focus on the FTD variants; the bvFTD patients fit best in the future prediction model, and the nfvPPA patients were the worst. Our results align with previous studies showing that FTD is phenotypically heterogeneous [21, 22]. and support that an independent predictive model should be created for each FTD phenotypic variant. Similarly, in a recent study of genetic FTD, Poos et al. [43], identified differences between the three major FTD gene mutation carriers' trajectories, suggesting that each genetic FTD subtype should also be modeled separately. The fit showed more FTD heterogeneity than AD at baseline and longitudinal levels. Overall, the proposed models could be the starting point to be able to differentiate different subtypes or dementias through the estimation of their CTh values or variabilities. Thus, further studies with a bigger cohort should study this point in detail.

Our study has some limitations. One of the major limitations of the study is the sample size. The sample size limited the generation of different CTh models for each FTD variant, especially all models at the third visit. However, the unicentric nature of the study, even if limited in the sample size, also provided homogeneity to the data acquisition. We only tested the effect of two selected neurodegeneration biomarkers in the individual residuals from their disease model. The selection of these two biomarkers was, at a certain point, arbitrary. Future studies could evaluate whether other markers could better explain the individual variability.

In conclusion, SVR provides the opportunity to generate CTh disease models to predict longitudinal changes and to study individual variability in AD, FTD, and healthy individuals and their relationships with cognitive features and biomarkers.

Conflict of Interest

The authors declare that the research was conducted without any commercial or financial relationships that could be construed as a potential conflict of interest.

Figures & Tables

Table 1: Group summaries are given as each measure's mean and standard deviation. Differences between groups are calculated using Fisher's Test for sex or the ANOVA Test for the rest of the variables. Significant group differences are highlighted in bold, and pairwise differences were measured with a Benjamini-Hochberg correction p-value. HC: healthy controls, AD: Alzheimer's disease, FTD: frontotemporal dementia, MMSE: Mini-Mental State Examination, NfL: neurofilament light chain.

	HC	**FTD**	**AD**	**HC-FTD p-value**	**HC-AD p-value**	**FTD-AD p-values**
N at first MRI	122	88	169	------	------	------
N at second MRI	88	27	29	------	------	------
N at third MRI	49	9	------	------	------	------
Sex at first MRI, Men/Women	47/75	43/45	65/104	0.24	1.0	0.24
Sex at second MRI, Men/Women	29/59	14/13	12/17	0.33	0.59	0.59

Abstract

Alzheimer's disease (AD) and frontotemporal dementia (FTD) are common causes of dementia with partly overlapping, symptoms and brain signatures. There is a need to establish an accurate diagnosis and to obtain markers for disease tracking. We combined unsupervised and supervised machine learning to discriminate between AD and FTD using brain magnetic resonance imaging (MRI). We included baseline 3T-T1 MRI data from 339 subjects: 99 healthy controls (CTR), 153 AD and 87 FTD patients; and 2-year follow-up data from 114 subjects. We obtained subcortical gray matter volumes and cortical thickness measures using FreeSurfer. We used dimensionality reduction to obtain a single feature that was later used in a support vector machine for classification. Discrimination patterns were obtained with the contribution of each region to the single feature. Our algorithm differentiated CTR versus AD and CTR versus FTD at the cross-sectional level with 83.3% and 82.1% of accuracy. These increased up to 90.0% and 88.0% with longitudinal data. When we studied the classification between AD versus FTD we obtained an accuracy of 63.3% at the cross-sectional level and 75.0% for longitudinal data. The AD versus FTD versus CTR classification has reached an accuracy of 60.7%, and 71.3% for cross-sectional and longitudinal data respectively. Disease discrimination brain maps are in concordance

with previous results obtained with classical approaches. By using a single feature, we were capable to classify CTR, AD, and FTD with good accuracy, considering the inherent overlap between diseases. Importantly, the algorithm can be used with cross-sectional and longitudinal data.

1 | INTRODUCTION

Alzheimer's disease (AD) and frontotemporal dementia (FTD) are common forms of dementia, with different, but partly overlapping, symptoms, and brain signatures. This complicates the differential diagnosis and might lead to misdiagnosis (Balasa et al., 2011; Mendez, 2006). On the other hand, accurate characterization of longitudinal trajectories is needed for prognosis and disease tracking purposes. In recent years, clinical studies have been complemented with automated or semiautomated algorithms, which hold promise toward computer-aided diagnosis. In this line, machine learning (ML) techniques use clinical and biomarker data to learn patterns that can be used as an aid for differential disease diagnosis and tracking.

Magnetic resonance imaging (MRI) has been widely used to detect disease-specific brain changes across different neurodegenerative disorders. Concretely, using structural MRI, studies have described patterns of cortical thickness (CTh) and gray matter (GM) volume loss both in AD and FTD when compared separately with healthy populations (Bocchetta et al., 2021; Canu et al., 2017; Contador et al., 2021; Möller et al., 2013). In addition, in a previous study including both diseases, we showed that distinct brain atrophy patterns could potentially help in differentiating AD and FTD (Falgàs et al., 2020). More recently, measures derived from MRI have been used within ML algorithms to differentiate these diseases (Bron et al., 2017; Li et al., 2021; Möller et al., 2016; Penny et al., 2007). These approaches have shown good results. However, the large number of features needed can result in computationally expensive methods that are difficult to implement in a clinical setting. In addition, obtaining spatial patterns of the features driving classification can be challenging in some cases. These two issues limit the applicability and interpretability of the algorithms.

Besides the description of atrophy patterns at a specific time point, longitudinal neuroimaging studies have gained popularity in AD and FTD (Bejanin et al., 2020; Irish et al., 2018; Sintini et al., 2020). Using structural MRI, studies have described the trajectories of GM volume and CTh loss with time, providing valuable information on the characterization of disease trajectories and validation of prognostic biomarkers (Risacher et al., 2010; Storsve et al., 2014). When compared with cross-sectional studies, longitudinal designs can explore the large heterogeneity of the effect of between-subject brain changes which requires repeated measures and longitudinal designs (Bernal-Rusiel et al., 2013; Thompson et al., 2011). Thus, while cross-sectional studies depict patterns of differential or overlapping brain atrophy, longitudinal studies are needed to understand the differences in disease trajectories. In the context of ML, although longitudinal data are sometimes used for diagnostic confirmation and/or for exploring the predictive values of baseline acquisitions, few approaches include longitudinal data in the training to improve the models.

In this study, we developed a classification algorithm using cross-sectional and longitudinal MRI data from 399 subjects, including AD and FTD patients and healthy controls (CTR). We implemented a feature reduction algorithm using unsupervised techniques followed by a widely used classifier, namely the support vector machine (SVM). Besides maximizing classification performance, by studying the weights of the features from the unsupervised part, we aimed to investigate the brain patterns that collected a higher amount of variance for the different classification settings, thus providing interpretability to our results.

2 | MATERIALS AND METHODS

2.1 | Participants

We selected 339 subjects prospectively recruited from the Alzheimer's disease and other cognitive disorders unit of the Hospital Clínic de Barcelona (HCB), all having a complete clinical work-up and at least one 3T high-resolution structural MRI scan. Additionally, a subset of subjects underwent a second acquisition after ~2 years. Participants were classified into three groups:

- AD: patients who presented AD biomarker profiles suggesting underlying AD neuropathology (*abnormal amyloid and tau*, A + T+) with neurodegeneration (N+) according to National Institute on Aging/Alzheimer Association Research Framework 2018 (Jack et al., 2018) and Mini-Mental State Examination (MMSE) ≥ 18. They also fulfilled diagnostic criteria for mild cognitive impairment due to AD or AD mild dementia (Albert et al., 2011; McKhann et al., 2011).
- FTD: patients who met diagnostic criteria for either behavioral variant frontotemporal dementia (bvFTD) or primary progressive aphasia (PPA), including semantic variant PPA (svPPA), and nonfluent variant PPA (nfvPPA) (Gorno-Tempini et al., 2011; Rascovsky

10970193, 0, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/hbm.26205 by Readcube (Labtiva Inc.), Wiley Online Library on [20/01/2023]. et al., 2011). FTD showed normal values for AD cerebrospinal fluid (CSF) biomarkers.

- CTR: healthy adults having cognitive performance within the normative range (cutoff 1.5 SD from the normative mean) and normal levels of AD CSF biomarkers.

Subjects were collected as part of other ongoing and past studies within the HCB. All were approved by the HCB Ethics Committee and all participants gave written informed consent.

2.2 | MRI acquisition

A high-resolution 3D structural data set (T1-weighted, MP-RAGE, repetition time = 2.300 ms, echo time = 2.98 ms, 240 slices, field-of-view = 256 mm, voxel size = 1 × 1 × 1 mm) was acquired for each individual at each time point in a 3T Magnetom Trio Tim scanner (Siemens Medical Systems, Germany) or in a 3T Prisma scanner (Siemens Medical Systems, Germany) at HCB using equivalent acquisition protocols. Before these analyses, we performed tests to evaluate the interscanner variability (results can be found in Supplementary Material S1), and we found low variability induced by the scanner.

2.3 | MRI processing

We used the processing stream available in FreeSurfer version 6.0 (http://surfer.nmr.mgh.harvard.edu.sire.ub.edu/) to perform cortical reconstruction and volumetric segmentation of the T1-weighted acquisitions. For longitudinal data, we used the longitudinal stream in FreeSurfer. All FreeSurfer preprocessing steps are reported in detail elsewhere (Fischl & Dale, 2000; Fischl et al., 2004; Reuter et al., 2012). Briefly, FreeSurfer allowed us to generate automated CTh maps and segmentation of the subcortical structures. From reconstructed data, we obtained global measures of mean CTh and GM volumes of the left and right hemispheres (lh and rh). In addition, we used the summary measures of mean CTh in 68 cortical parcellations and GM volumes of 17 subcortical structures, all derived from atlases available in FreeSurfer (Desikan et al., 2006; Seidman et al., 1997). Volume measures were normalized by the estimated intracranial volume. All images and individual segmentations were visually inspected and manually corrected if needed.

2.4 | Cross-sectional study: Brain signatures and classification performance

We used all the CTh values and subcortical volumes at baseline obtained with FreeSurfer to create our ML pipeline. We introduced the global and regional measures of both hemispheres (rh and lh) separately leading to a total of 103 values per subject. Subcortical regions were normalized using the intracranial volume and then all values (subcortical volumes and CTh measures) were converted to z-score. Therefore, the features of our ML algorithm were the subcortical volumes and the CTh measures transformed to z-scores obtained after processing the T1-weighed MRI images.

Firstly, we performed a principal component analysis (PCA) to reduce the number of regional measures (all CTh measures and all volumetric values) to a single feature, by keeping only the first principal component (PC). The first PC is the one with the highest value of explained variance, so it is the best choice to study the weights used in the transformation while keeping good classification accuracy. The weights to obtain this first PC will be used to provide a regional interpretation of the classification results. Second, this feature was introduced into a SVM algorithm to perform classifications between the three groups and between pairs of groups. Eventually, the weights of the PCA were used to create disease-specific patterns. These patterns, allow having an interpretable ML algorithm that returns the accuracy and the associated patterns of the classification between groups. So, the proposed pipeline is not only focused on obtaining the best accuracy, but it also focuses on giving explainability to the ML algorithm.

To address circularity in the PCA and to avoid overfitting, we implemented all the steps in a cross-validated setting, in which train data was used in the entire PCA + SVM, and a group of subjects was hold-out to be used as test data. For testing, original data were projected into the PCA space to obtain the unique feature and this was used in the SVM classification. Overall performance was assessed using k-fold cross-validation with 20 iterations of the procedure explained above. Figure 1 shows a schematic representation of the algorithm. Additionally, the SVM hyperparameters: kernel (options: linear, rbf, and polynomial), *C* (values = [0.1,1, 10, 100, and 1000]), and gamma (values = [1, 0.1, 0.01, and 0.001]) were introduced with a Grid Search using an additional cross-validation of 10, with the train set. The algorithm was implemented in Python version 3.8 (www.python.org), and we used the library scikit-learn (Pedregosa et al., 2011) for PCA, Grid Search, and SVM.

To assess the effect of age in the classification, we performed two complementary analyses: (1) we evaluated if age itself was able to classify the different groups; (2) We repeated all analyses by adding age as a feature together with all the regions. To assess the effect of sex in the classification we repeated all analyses by adding sex as a feature together with all the regions.

2.5 | Longitudinal study: Brain signatures and classification

We used all global and regional volumes and CTh measures derived from the FreeSurfer longitudinal stream for the longitudinal classification analysis. As in the cross-sectional analysis, we introduced the measures of both hemispheres (rh and lh) separately, subcortical regions were divided by intracranial volume, and all values were converted to z-score.

Here, the overall pipeline also consisted of an unsupervised algorithm followed by an SVM classification. For the unsupervised part,

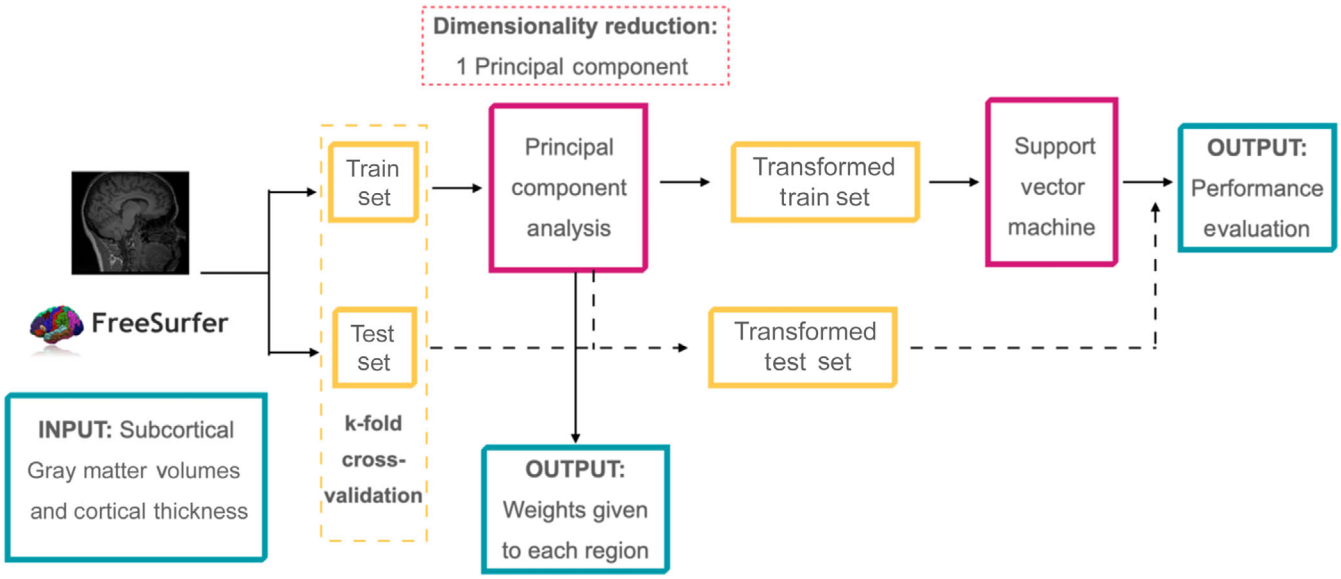

FIGURE 1 Machine Learning Algorithm scheme

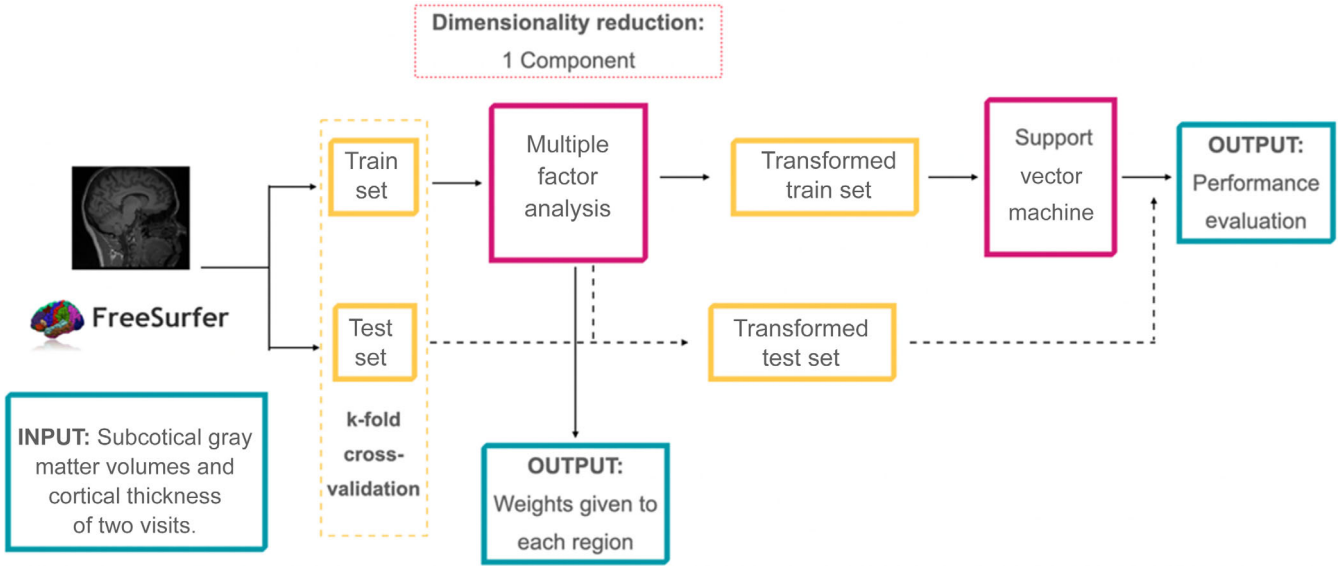

FIGURE 2 Longitudinal Machine Learning Algorithm scheme

we performed a multiple factor analysis (MFA), which is a generalization of PCA. MFA allows implementing a factor analysis with repeated samples (i.e., the same measures for different time points for each subject; Abdi et al., 2013). As before, we only kept the first component. We kept the first component with the same objective as we did with the PCA in the cross-sectional analyses. The weights to obtain this first component will give us the interpretability of the classification results of the algorithm. Then, this first component was introduced to the SVM algorithm. Here, the use of MFA facilitates the creation of a longitudinal ML in the SVM context, while keeping the interpretability of results. As before, overall performance was assessed using k-fold cross-validation with $k = 20$, in which test data was not included in any of the procedures within the pipeline (MFA and SVM). As an internal quality control, we revised the number of subjects included in the train/test set for each iteration, and we observed that they were equally distributed across iterations. Figure 2 shows a scheme of the algorithm.

With the objective to study how the longitudinal data can help to improve the classification in ML algorithms and how should be introduced to the algorithm, different settings were considered for the longitudinal analysis: (1) including all regional measures from time point 1 and time point 2 as different observations for each subject in the MFA decomposition. (2) including all measures from each time point together with a *change* variable (computed as time point2–time point1) for each region in the MFA decomposition. (3) using only the change variable in a standard PCA analysis. So, this setting will be the equivalent of a study with longitudinal data but analyzed at a cross-sectional level. In addition, to allow comparison with the cross-

10970193, 0, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/hbm.26205 by Readcube (Labtiva Inc.), Wiley Online Library on [20/01/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

sectional analysis we performed a PCA decomposition of the data from time point 1 with the subsample having a longitudinal acquisition.

Finally, for each of the four decomposition settings mentioned above, we used the weights of the obtained component from the MFA/PCA to create disease-specific patterns. The SVM optimal parameters were obtained with a Grid Search with cross-validation of 10, with the train set.

The algorithm was implemented in Python version 3.8 we used the libraries prince (https://pypi.org/project/prince/) for MFA and scikit-learn (Pedregosa et al., 2011) for PCA, Grid Search, and SVM.

3 | RESULTS

3.1 | Sample demographics

Of the 339 subjects included in the analyses, 153 were AD patients ($n = 20$ with longitudinal data); 87 were FTD ($n = 26$ with longitudinal data), and 99 were CTR ($n = 68$ longitudinal). The FTD group included subjects with 49 bvFTD patients ($n = 14$ longitudinal data), 20 svPPA patients ($n = 7$ longitudinal data), 17 nfvPPA patients ($n = 4$ longitudinal data), and 1 unspecified PPA patient ($n = 1$ longitudinal data). Demographic information and group statistics are shown in Table 1. In summary, there was a significantly greater proportion of men in the FTD group compared with the AD and CTR groups. In addition, CTR subjects were slightly younger than AD and FTD groups ($p < 0.05$) at the first visit. However, there were no differences in age for the second visit. The time between scanners was lower in the FTD group compared with AD and CTR ($p < .0001$) but did not differ between AD and CTR.

3.2 | Cross-sectional analyses: Classification

Our algorithm had an accuracy of 83.3% ± 12.7% in the CTR versus AD classification, 82.1% ± 14.7% for CTR versus FTD, 63.3% ± 9.1% for AD versus FTD, and 60.7% ± 12.7% when discriminating the three groups. Including age or sex in the algorithm led to similar results (see Supplementary Material S1)

3.3 | Cross-sectional analyses: Brain patterns and relevant features

The weights of each of the regional measures (CTh cortical regions and GM volumes for subcortical regions) were obtained as their contribution to the main feature (i.e., the first component). Figure 3 shows these PCA weights for the separate analysis of CTR versus AD and CTR versus FTD. As all algorithms were cross-validated using k-fold, these patterns show the mean weights obtained with all the train sets across iterations.

As can be seen in Figure 3, for AD, the three most important regions were rh supramarginal, lh supramarginal, and rh precuneus. For the FTD group, these were rh supramarginal, rh superior frontal, and rh inferior parietal. The complete list of regions with their associated weights for each setting is shown in Supplementary Material S1.

3.4 | Longitudinal analyses: Classification

First, when using the two time points separately for each subject in the MFA, we obtained an accuracy of 90.0% ± 14.7% in the CTR versus AD classification, 88.0% ± 16.4% for CTR versus FTD, 75.0% ± 36.9% for AD versus FTD, and 71.3% ± 13.1% for the three-group classification (Table 2)

Including change as an additional measure for each subject and region led to higher classification scores for CTR versus AD and the three-group classification. The accuracies were 94.5% ± 11.8% in the CTR versus AD classification, 87.8% ± 17.8% for CTR versus FTD, 60.8% ± 33.4% for AD versus FTD, and 77.7% ± 19.0% when discriminating the three groups. Interestingly, including change in the algorithm increased the accuracy for CTR versus AD and decreased the accuracy for CTR versus FTD. Including age or sex in all the longitudinal analyses led to similar results (see Supplementary Material S1)

TABLE 1 Group summaries are given as the mean and the SD of each measure.

				CTR–AD	CTR–FTD	AD–FTD
	CTR	AD	FTD	*p*-value	*p*-value	*p*-value
N at first MRI	99	153	87	–	–	–
N at second MRI	68	20	26	–	–	–
Sex at first MRI, men/women	30/69	59/94	47/40	.22	**.005**	**.03**
Sex at second MRI, men/women	18/50	10/10	15/11	.09	**.02**	.77
Age at first MRI, years (SD)	60.2 (10.5)	64.3 (9.7)	63.6 (8.3)	**.003**	**.03**	.5
Age at second MRI, years (SD)	65.0 (7.2)	62.1 (4.5)	63.8 (5.9)	.3	.5	.5
Time between MRIs, years (SD)	2.1 (0.4)	1.9 (0.3)	1.4 (0.5)	.3	**2.5 e-9**	**4.7 e-5**

Note: Differences between groups are calculated using Fisher test for sex and the ANOVA test for the rest of the variables. Significant group differences are highlighted in bold, and pairwise differences were measured with Benjamini–Hochberg correction (*p*-values threshold .05).

The cool color scale represents negative weights, and the warm scale represents positive weights within the component

TABLE 2 Classification performance of the different approaches.

		Longitudinal reduced sample			
	Cross-sectional all subjects (%)	Tp1, Tp2 (%)	Tp1, Tp2, change (%)	Only change (%)	Baseline of the longitudinal sample
CTR vs. AD	83.3 ± 12.7	90.0 ± 14.7	**94.5 ± 11.8**	86.5 ± 13.2	79.5 ± 9.8
CTR vs. FTD	82.1 ± 14.7	**88.0 ± 16.4**	87.8 ± 17.8	80.0 ± 15.4	81.0 ± 16.0
AD vs. FTD	63.3 ± 9.1	**75.0 ± 36.9**	60.8 ± 33.4	58.3 ± 32.2	67.5 ± 32.2
CTR vs. AD vs. FTD	60.7 ± 12.7	71.3 ± 13.1	**77.7 ± 19.0**	46.7 ± 21.2	59.7 ± 10.4

Note: The best accuracy for each group is highlighted in bold.
Abbreviations: AD, Alzheimer's disease; CTR, controls; FTD, frontotemporal dementia, Tp1, timepoint 1; Tp2, timepoint 2.

When including only change as a feature for each region (i.e., without the individual time point data), we obtained lower classification scores compared with the full-longitudinal setting. The classification scores were: 86.5% ± 13.2% in the CTR versus AD classification, 80.0% ± 15.4% for CTR versus FTD, 58.3% ± 32.2% for AD versus FTD, and 46.7% ± 21.2% for the three-class classification. This result indicates that this variable is not the unique source of discrimination power across groups. However, we observed that including it in the longitudinal study together with the measures at each time point was beneficial for classification

Finally, to be able to directly compare the two approaches, we repeated the cross-sectional analyses for the baseline data of the subjects that had longitudinal data available. We obtained a cross-sectional accuracy of 79.5% ± 9.8% in the CTR versus AD classification, 81.0% ± 16.0% for CTR versus FTD, 67.5% ± 32.2% for AD versus FTD, and 59.7 ± 10.4% for the three-class classification. These results highlight the increase in performance for the longitudinal approach when compared with a cross-sectional approach with an equivalent sample. Table 2 shows a summary of all the accuracies for each analysis and comparison

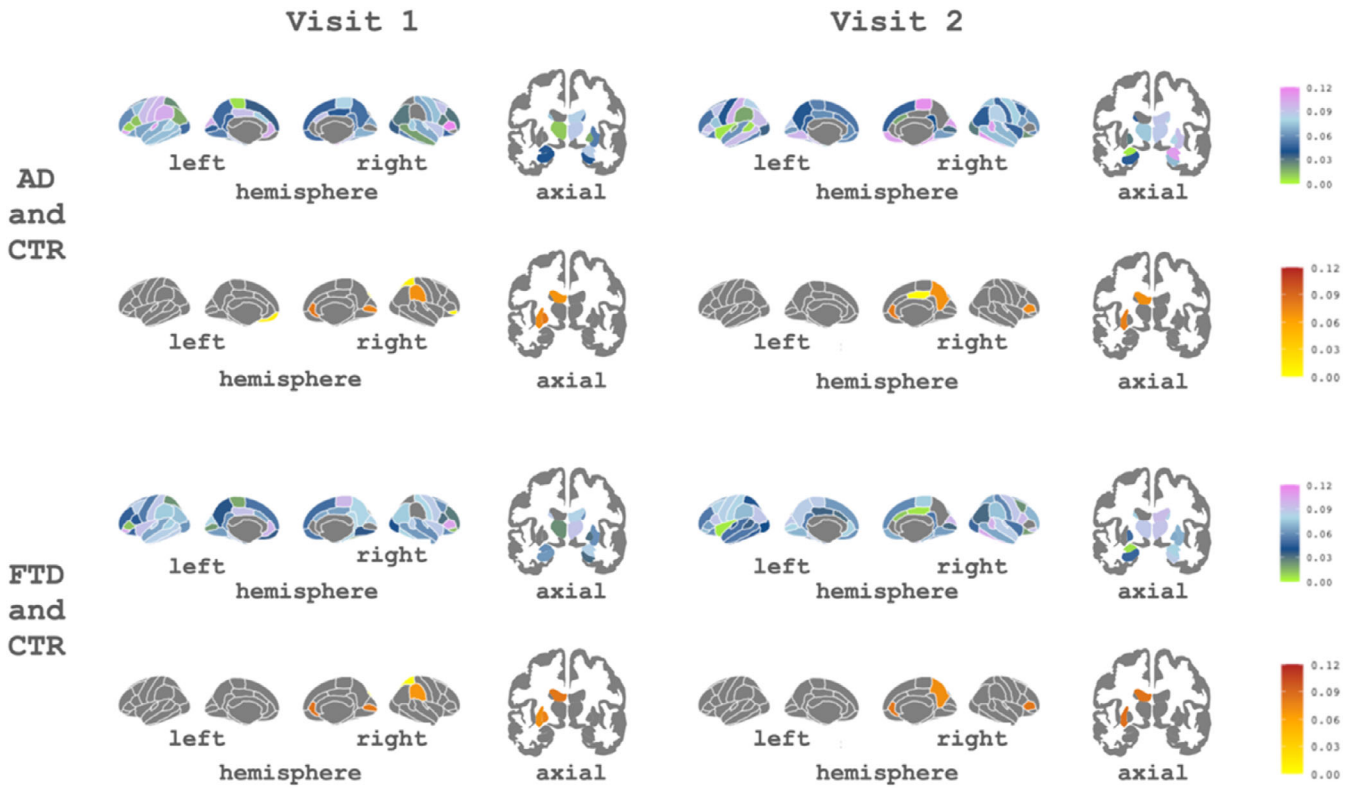

FIGURE 4 Subcortical and cortical patterns of the contributions of the first component associated with Alzheimer's disease (AD) and frontotemporal dementia (FTD) for both visits. The cool color scale represents negative weights, and the warm scale represents positive weights within the component

3.5 | Longitudinal analyses: Brain patterns and relevant structures

The contributions of each brain region (CTh cortical regions and GM volumes for subcortical regions) to the first MFA component are shown in Figure 4. Using these weights, we created a pattern for each comparison and visit: CTR versus AD and CTR versus FTD. As before, patterns were obtained with the mean weights obtained with all train sets across iterations.

As can be seen in Figure 4, for the longitudinal analysis the most important regions for differentiating AD were rh pars triangularis, rh entorhinal, and lh transverse temporal from Visit 1, and rh paracentral, rh inferior temporal, and rh amygdala from Visit 2. For FTD, these were rh pars triangularis, lh pars orbitalis, and lh rostral anterior cingulate from Visit 1 and rh temporal pole, rh inferior temporal, and rh bankssts from Visit 2. The complete list of features and associated weights for each comparison can be found in Supplementary Material S1.

4 | DISCUSSION

In this study, we show the utility of machine learning approaches for the differential diagnosis of AD and FTD. We used a combination of unsupervised and supervised techniques that allowed (1) reducing all subcortical GM volumes and CTh measures from MRI into a single feature and (2) obtaining blind classifications from MRI data while providing meaningful atrophy patterns at the group level using the weights of the unsupervised part of the algorithm. We implemented two equivalent algorithms for cross-sectional and longitudinal data, and we observed that longitudinal approaches outperformed cross-sectional analyses in differentiating AD and FTD.

At the cross-sectional level, we demonstrated that ML can be used to support clinical diagnosis using a method that is not computationally expensive. Previous ML neuroimaging studies with cross-sectional structural MRI data have shown accuracies between 80% and 95% for AD versus CTR, 72%–88% for FTD versus CTR, and 69%–89% for AD versus FTD (Bron et al., 2017; Klöppel et al., 2008; Möller et al., 2016). In the case of the three-class classification, Bron et al. (2017) reported an accuracy of 70%. In our cohort, we obtained accuracy scores that are in agreement with these studies. Our study has a higher sample size than those mentioned above and differs in two important methodological aspects: first, we used a feature reduction algorithm that results in a single component being fed into the classification stage. This component encompasses information from all CTh values and GM volume measures. Even if there is an obvious risk of losing information in this step, we demonstrated that it is still useful for discrimination, while reducing the computational cost. Second, our FTD group included patients with both PPA and bvFTD variants, not only bvFTD patients as in some of the abovementioned

10970193, 0, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/hbm.26205 by Readcube (Labtiva Inc.), Wiley Online Library on [20/01/2023]. studies. Even if further studies with similar algorithms should attempt to differentiate disease subtypes, we believe that our approach can be very useful to support differential diagnosis across diseases. Noteworthy, the wide range of misclassified subjects both in ours in previous studies suggests that some heterogeneities and overlaps need to be further explored (Habes et al., 2020).

We developed an algorithm that used longitudinal data for training the classification models, which resulted in a noticeable increase in classification accuracy for all comparisons, increasing up to 15% of the overall accuracy score. Only a few studies have used longitudinal data in ML algorithms. For example, previous studies reported accuracies between 80% and 94% for AD versus CTR (Gavidia-Bovadilla et al., 2017; Guo et al., 2020; Zhang et al., 2017). In our cohort, we obtain accuracy scores of 90% and 95% for this specific comparison, outperforming previous approaches. To our knowledge, no previous studies have used longitudinal data to differentiate FTD versus CTR or AD versus FTD. Our approach uses the MFA decomposition, which captures the variance of the data while modeling intra-subject variability.

The accuracy obtained in all the longitudinal experiments suggests that the proposed methodology is useful to support the diagnosis problem of distinguishing AD from FTD. Longitudinal analyses allowed studying disease change and disease trajectories. Here, we first applied the ML algorithm combining all longitudinal data in a repeated measures fashion (Visit 1 plus Visit 2). We then tested the algorithm using the longitudinal data (Visit 1 and Visit 2) in combination with the variable change that was the difference between both visits. We observed that including the change variable in the algorithm boosted the accuracy for CTR versus AD and worsened the accuracy for CTR versus FTD. This could indicate that in AD patients the change variable has higher discriminative power. On the contrary, in FTD the change variable did not add discriminative power (indeed, there is a slight decrease in accuracy), indicating that the patterns themselves provide more discriminability than the change. This finding could be associated with the fact that FTD patients could show floor effect in atrophy rates due to an advanced stage of disease, while AD patients included in this study might be in a less advanced stage (Pankov et al., 2016). Finally, as regards the abovementioned results, we acknowledge that the change variable, computed as a difference, might add collinearity to the algorithm. However, by including it, we were able to make guesses about the different spatial patterns being important for classification.

Besides maximizing performance, we were interested in depicting the spatial patterns that drive accuracy for each classification setting. In ML, this represents a crucial step for developing algorithms that are interpretable at the biological and pathological levels (Stiglic et al., 2020). Here, we used the weights of the PCA/MFA components to identify the regions that contributed the most to the group variances. To add explainability to our algorithm, we studied the most important regions providing classification between pathologies. In general, we found widespread brain patterns of variance, with common AD/FTD regions appearing within the ones on the top of the lists, depicting pathological patterns in concordance with the literature (Möller et al., 2016; Rabinovici et al., 2008). However, our classification feature was obtained from the PCA, and therefore it includes contributions across all brain regions, accounting for both overlapping and differential patterns across disorders. ML techniques search for robust interactions between features (in our case the brain regions), so it is plausible that AD and FTD patterns present both differential and overlapping regions. Previous works (Davatzikos et al., 2008; Falgàs et al., 2020; Laakso et al., 2000) have also found some overlapping patterns of degeneration across disorders. Overall, we believe that the joint analysis of overlapping patterns (i.e., indicating common neurodegeneration) and specific regional alterations will be crucial in future works investigating differential diagnosis.

We developed an ML algorithm for differential diagnosis of FTD and AD with good to excellent accuracy. Our algorithm combines unsupervised and supervised methodologies. In addition, we adapted our algorithms to longitudinal data, which was not included in previous works in the field (Bron et al., 2017; Chagué et al., 2021; Klöppel et al., 2008; Möller et al., 2016). Therefore, the main novelty is the combination of advanced methods (PCA/MFA and SVM) together with the use of longitudinal data, a key point to understanding neurodegenerative diseases (Clifford et al., 1999). Moreover, the PCA was not only used for the feature reduction step, as in previous studies (Bachli et al., 2020; Davatzikos et al., 2008; Kim et al., 2019), but also for obtaining the weights of the features for interpreting the findings.

Our study has some limitations. Regarding the sample size: First, it is important to consider that our sample size at baseline, is lower compared with the sample size which can be obtained in a multicentric study. However, all the data has been acquired in the same center, allowing us to have the same MRI scanner protocol and the same clinical criteria for the diagnosis. Another limitation is the relatively small sample size at the follow-up visit, in some analyses, especially for the comparison between AD and FTD, the number of subjects was low, due to the difficulty of obtaining longitudinal samples in these dementias. Regarding the MRI data, it is known that the combination of different modalities of MRI, such as diffusion tensor imaging (DTI), resting-state, amyloid positron emission tomography, or arterial spin labeling could improve the accuracy scores (Agostinho et al., 2022; Bron et al., 2014, 2017), while in our case we only used structural MRI. Thus, as future work, we could include some of these image modalities in our algorithm. Finally, the different clinical variants in the FTD group (bvFTD and PPA) were studied as a single group and there is the possibility that our results are biased by the different FTD atrophy patterns. Due to sample size limitations, it was impossible to subdivide the FTD group to study in detail the different variants of the pathology. Future studies taking into consideration this point should be considered.

In our study, we focused on differentiating AD and FTD using ML on MRI data. Other studies have reported differences between these pathologies using a wide range of methods and MRI sequences. For example, the work of Du et al. (2007) used structural MRI to compare regional CTh between AD and FTD and their relationship with neuropsychological scores at a vertex-wise level. They found that FTD patients, compared with AD patients, had a thinner cortex in parts of

10970193, 0, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/hbm.26205 by Readcube (Labtiva Inc.), Wiley Online Library on [20/01/2023]. the bilateral parietal and precuneus regions. Similarly, Steketee et al. (2016) used perfusion and structural MRI to differentiate AD and FTD. They studied the sensitivity, specificity, and diagnostic performance of the different regions and found that AD patients, compared with FTD patients, showed hypoperfusion in the posterior cingulate cortex. However, they also found that regional atrophy did not differ between AD and FTD. In this sense, we could differentiate AD and FTD with atrophy values, suggesting that ML techniques, that incorporate information across the whole brain, might be more sensitive. Finally, Avants et al. (2010) used sparse canonical correlation analysis with DTI and T1-weighed MRI data to identify patterns of reduced white matter (WM) integrity for AD and FTD. They found that, in FTD, frontal and temporal degeneration is correlated across modalities. In AD, they reported a significant association between CTh and WM in parietal and temporal regions. Considering all these studies, in future work, we aim to add different MRI modalities and other clinical variables to our algorithm.

5 | CONCLUSION

In conclusion, our study leads to three important points: First, the combination of PCA or MFA and SVM successfully separates patients with AD or FTD from CTR subjects. Second, they perform well in the differential diagnosis of two pathologies (AD vs FTD). Thirdly, the follow-up visits are beneficial in ML algorithms to distinguish these pathologies, especially AD. All these points suggest an important breakthrough in computer-aided diagnostic image analysis for clinical research and practice.

Supplementary Material

Intra-Scanner Variability

We studied 3 MRI-longitudinal datasets with 2 time-points, separated 2 years, all having available T1-weighted scans, with equal or equivalent acquisition protocols before and after a scanner upgrade. Being 'scanner 1' a 3T Siemens TrioTim MRI scanner and 'scanner 2' a 3T Siemens Prisma scanner, the groups were as follows: (1) A group of 14 healthy controls (median and IQR age: 58.4 [54.7, 61.4]) scanned with scanner 1 at both time points (CTR); (2) a group of 17 healthy controls (median and IQR age: 59.7 [49.0, 60.9]) scanned at baseline with scanner 1 and after 2 years with scanner 2 (CTRc), and (3) a group of 12 AD patients (median and IQR age: 60.4 [58.0, 65.8]), scanned with scanner 1 at both time points. We used the longitudinal processing stream of FreeSurfer to obtain summary measures, including subcortical GM volume and cortical thickness (CTh) using the same atlases as the main manuscript. We studied the intra-class correlation coefficient (ICC) to assess the reliability of the metrics for CTR and CTRc groups. We calculated the percent difference (PcD) to obtain the relative difference of GM measures between time points, for all groups. With the PcD measure, we aimed to study the magnitude of the changes due to the scanner in comparison with the effect of AD in atrophy. We further focused on hippocampal atrophy to provide a practical example, as it is considered a biomarker for AD.

We found that the ROI-CTh measures were the most affected by the scanner upgrade, with a mean ICC across regions of 0.8 and 0.92 for the CTRc and CTR groups respectively (36 out of 68 regions were significantly different). However, mean ICC values were close to 1 for both datasets for these metrics, indicating good reliability. As regards PcD, we consistently observed that longitudinal differences were stronger in AD than in CTR or CTRc groups (Figure 1). Mean PcD values for CTh (across parcellations) were: -0.20% for CTR, -1.53% for CTRc and -4.57% for AD. And mean PcD for subcortical GM volumes were (across atlas regions): -3.11% for CTR, -2.76% for CTRc and -10% for AD. Hippocampal atrophy was similar between CTR and CTRc with values close to zero, with no significant differences between them. In AD, hippocampal volume loss was stronger, showing significant differences between CTR and CTRc (Figure 2).

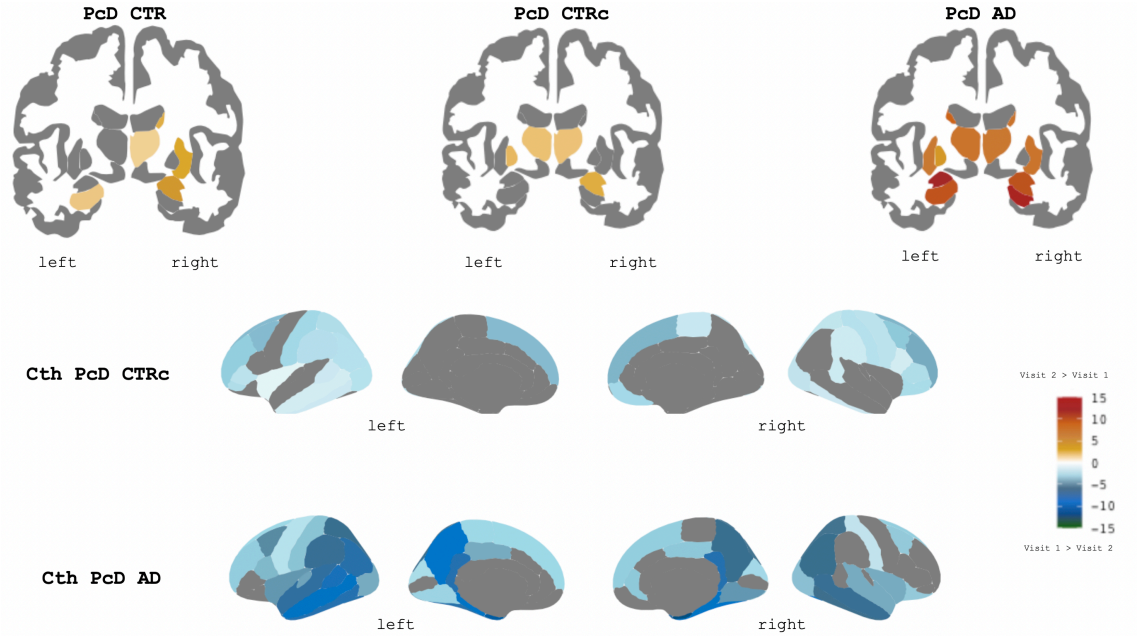

Figure 1: Mean PcD values for CTR, CTRc, and AD. Only significant regions are shown. The cool color scale represents Visit 1 > Visit 2 and the warm scale represents Visit 2 > Visit 1 within the PcD

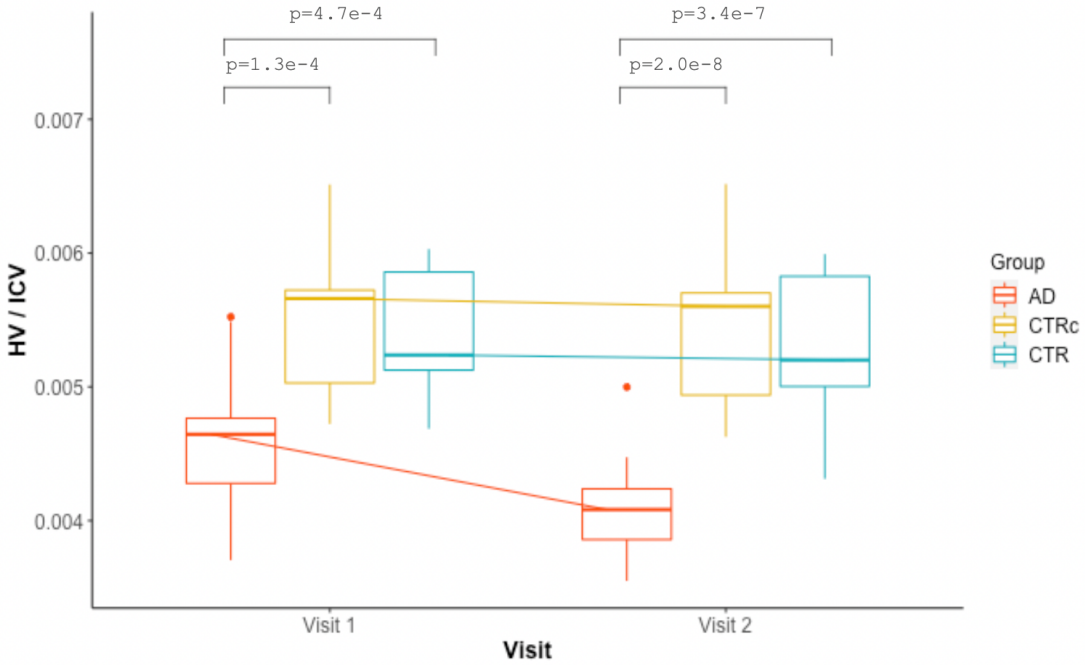

Figure 2: Boxplot of the HV normalized by the intracranial volume (ICV) for each visit. Pairwise comparisons show significant differences in some comparisons.

Disease Classification with Age: Cross-sectional study

The ML algorithm, which combines all cortical CTh values and the subcortical GM volumes (obtained with FreeSurfer) including age, had the following accuracy: 81.8 ± 13.2 % in the CTR vs AD classification, 82.6 ± 14.8 % for CTR vs FTD, 62.1 ± 7.8 % for AD vs FTD and 61.9 ± 10.5 % when discriminating the 3 groups.

Disease Classification with Sex: Cross-sectional study

The ML algorithm, which combines all cortical CTh values and the subcortical GM volumes (obtained with FreeSurfer) including the sex variable, had the following accuracy: 81.8 ± 14.2 % in the CTR vs AD classification, 82.6 ± 14.8 % for CTR vs FTD, 61.3 ± 11.6 % for AD vs FTD and 61.1 ± 8.5 % when discriminating the 3 groups.

Cross-sectional analyses: Brain patterns and relevant regions

The complete list of regions ordered from most to least important for AD and CTR is shown in Table 1.

Table 1: Relevant regions for the AD and CTR classification.

Longitudinal Classification with Age

The ML longitudinal algorithm, combining all cortical CTh values and the subcortical GM volumes (obtained with FreeSurfer) including age, had the following accuracy: 90.0 ± 14.7 % in the CTR vs AD classification, 88.0 ± 16.4 % for CTR vs FTD, 72.5 ± 40.2 % for AD vs FTD and 70.5 ± 13.9 % when discriminating the 3 groups.

The ML longitudinal algorithm combining all cortical CTh values and the subcortical GM volumes at each visit, the difference between both visits for each measure, and age, had the following accuracy: 93.5 ± 12.2 % in the CTR vs AD classification, 85.5 ± 18.7 % for CTR vs FTD, 60.8 ± 33.4 % for AD vs FTD and 79.3 ± 19.4 % when discriminating the 3 groups.

Disease Classification with Sex: Longitudinal

The ML longitudinal algorithm, which combines all cortical CTh values and the subcortical GM volumes (obtained with FreeSurfer) including the sex variable, had the following accuracy: 90.0 ± 14.7 % in the CTR vs AD classification, 88.0 ± 16.4 % for CTR vs FTD, 75.0 ± 36.9 % for AD vs FTD and 70.5 ± 13.9 % when discriminating the 3 groups.

Longitudinal analyses: Brain patterns and relevant regions

The complete list of regions ordered from most to least important for AD and CTR for visit 1 is shown in Table 3.

Table 3: Relevant regions for the AD and CTR classification for visit 1.

Keywords: Alzheimer's disease, frontotemporal dementia, magnetic resonance imaging, machine learning, CSF biomarkers, SVM, individual probability

Key points

- The classification between Alzheimer's disease and Frontotemporal dementia should account for probabilities.
- There is a gray zone of subjects with non-confident or unclear diagnoses that should be studied deeper.
- The availability of multimodal data contributes to improving diagnosis.

ABSTRACT

Introduction: Neuroimaging and fluid biomarkers are used in clinics to differentiate frontotemporal dementia (FTD) from Alzheimer's disease (AD) and other neurodegenerative and non-neurodegenerative disorders. We implemented a machine learning (ML) algorithm that provides individual probabilistic scores for these patients based on magnetic resonance imaging (MRI).

Methods: We used a calibrated classifier with a Support Vector Machine with MRI data. We obtained group classifications and individual probabilities associated with group correspondence. We used the individual probabilities to address the clinical problem of confidence in the diagnosis. We investigated whether combining MRI and cerebrospinal fluid (CSF) levels of Neurofilament light (NfL) and 14-3-3 could improve the diagnosis confidence.

Results: 215 AD patients (65 ± 10 years, 137 women), 103 FTD patients (64 ± 8 years, 49 women), and 173 CTR (59 ± 15 years, 106 women) were studied. With MRI data only, we obtained accuracies of 88% in the AD vs. healthy controls (CTR) classification, 87% for FTD vs. CTR, 82% for AD vs. FTD, and 80% when differentiating the three groups. A total of 74% of FTD and 73% of AD participants have a high (≥0.8) probability of accurate diagnosis in the FTD vs. AD comparison. Adding CSF-NfL and 14-3-3 levels did not improve the accuracy or the number of patients in the high diagnosis confidence group.

Conclusion: Our approach, using ML algorithms that provide individual probabilities, holds promise towards individual diagnoses, especially in doubtful cases as support to clinical findings or in settings with limited access to expert diagnoses.

1. INTRODUCTION

Alzheimer's Disease (AD) is the most frequent neurodegenerative disorder. Frontotemporal dementia (FTD) is also frequent in people younger than 65 years old and is the main differential diagnosis with AD in this age group. AD and FTD are characterized by prototypical clinical features and patterns of progressive brain atrophy that constitute the disease's fingerprint or signature. An early and accurate diagnosis is essential for treatment, prognosis, and genetic counseling. However, there is considerable individual variability in the clinical features, especially in the early stages. This limits the accuracy of the clinical diagnosis at this stage.

During the last two decades, fluid biomarker studies have substantially improved the diagnosis of neurodegenerative dementias. The current clinical criteria for AD diagnosis include cerebrospinal fluid (CSF) biomarkers, such as the amyloid-beta protein 42 (Aβ42), the total tau (t-tau), and phosphorylated tau (p-tau) [1, 2]. However, currently, FTD criteria do not include biochemical markers. Neurofilament light chain (NfL) levels, a marker of neuroaxonal damage, and 14-3-3 protein levels, a marker of synaptic-neuronal loss, have been both proposed as nonspecific neurodegeneration markers that could support the diagnosis of FTD, although their levels are also increased in AD compared to controls [3–6].

Magnetic Resonance Imaging (MRI) is broadly used in the study of AD and FTD, both at the research and the clinical levels. Visual evaluation of the atrophy pattern is mainly used in the clinical setting [7, 8]. Quantitative MRI studies have described patterns of cortical thickness and gray matter (GM) volume loss in AD and FTD at the group level when compared separately with healthy populations [9–14]. However, quantitative MRI studies are only scarcely used in clinics due to technical difficulties and limited accuracy in performing the diagnosis at the individual level.

A growing body of evidence supports the role of machine learning (ML) techniques using brain MRI [15–17] to support the clinical diagnosis of these two dementias [18–22]. Many studies have shown that a support vector machine (SVM) with neuroimaging data

differentiates AD or FTD patients from healthy controls [22–27]. However, fewer studies exist on the differential diagnosis of these two dementias, even though the clinical symptoms of FTD and AD can display a substantial overlap between them [28–30].

In this study, we aimed to develop a probabilistic computer-aided diagnosis of FTD and AD with MRI data to study the overlapping and differential brain patterns of these two neurodegenerative disorders. Then, we addressed the clinical problem of diagnosis confidence using individual prediction probabilities. We proposed investigating whether combining MRI and CSF biomarkers could help differentiate these two dementias and gain more confidence in the diagnosis.

2. MATERIALS AND METHODS

2.1. Participants

We recruited the participants from the Alzheimer's disease and other cognitive disorders unit of the Hospital Clínic de Barcelona (HCB), Barcelona, Spain. All participants underwent a complete clinical and cognitive evaluation and a 3T high-resolution structural MRI scan.

All AD participants fulfilled the criteria for mild dementia due to AD [1, 2] supported by the CSF biomarkers profile suggesting underlying AD neuropathology according to National Institute on Aging/Alzheimer's Association Research Framework 2018 [31]. The FTD participants fulfilled the diagnostic criteria for either behavioral variant frontotemporal dementia (bvFTD) or FTD-related primary progressive aphasia (PPA) phenotypes, including Semantic Variant Primary Progressive Aphasia (svPPA) and Nonfluent Variant Primary Progressive Aphasia (nfvPPA) [32, 33]. Healthy adults (CTR) had cognitive performance within the normative range.

The HCB Ethics Committee approved the study (HCB 2019/0105), and all participants gave written informed consent.

2.2 Biochemical markers

We used commercially available single-analyte enzyme-linked immunosorbent assay (ELISA) kits to determine levels of CSF NfL (IBL International, Hamburg, Germany) and CSF 14-3-3 (CircuLex, MBL International Corporation, Woburn, MA) at the Alzheimer's disease and other cognitive disorders unit laboratory, Barcelona, Spain.

2.3 MRI acquisition

We acquired a high-resolution 3D structural dataset (T1-weighted, MP-RAGE, repetition time = 2.300 ms, echo time = 2.98 ms, 240 slices, field-of-view = 256 mm, voxel size = 1 × 1 × 1 mm) for everyone at each time point in a 3T Magnetom Trio Tim scanner (Siemens Medical Systems, Germany) upgraded to a 3T Prisma scanner (Siemens Medical Systems, Germany) during the study.

2.4 MRI processing

We used the processing stream available in FreeSurfer version 6.0 (http://surfer.nmr.mgh.harvard.edu.sire.ub.edu/) to perform cortical reconstruction and volumetric segmentation of the T1-weighted acquisitions. FreeSurfer allowed us to obtain cortical thickness (CTh) maps and segment the subcortical structures [34, 35]. From reconstructed data, we got summary measures of mean CTh and GM volumes across the left and right hemispheres and summary measures of mean CTh in 68 cortical regions and GM volumes of 16 subcortical structures, all derived from atlases available in FreeSurfer [36, 37]. The estimated intracranial volume was used to normalize volume measures. All images and individual segmentations were visually inspected and manually corrected if needed.

2.5 MRI-based individual probabilistic classification algorithm

We used all CTh values, GM subcortical volumes, and the age of the participants to create our ML algorithm. We introduced the regional measures of both hemispheres separately, leading to a total of 84 features per subject (see Supplementary Material).

We first converted MRI data to z-scores. We implemented a calibrated classifier with an SVM as a base estimator to predict these values. For each classifier, we fitted a regression

that distributes the classifier's output to calibrate the probability between 0 and 1. We created classifiers for each pair of diagnostic groups (AD vs. CTR, FTD vs. CTR, and AD vs. FTD) and across the three groups (AD vs. FTD vs. CTR). Then, we subdivided the FTD group into bvFTD and PPA, and we used them as independent groups in a new set (AD vs. bvFTD, AD vs. PPA, CTR vs. bvFTD, CTR vs. PPA, and bvFTD vs. PPA). All the comparisons were performed with a 5-fold cross-validation to evaluate the performance of the classification. Then, we analyzed the importance of each region for the decision of the classification through a permutation feature importance estimation [38] using the test data of each run. The higher the weight, the larger the importance of the feature in the classification.

We obtained individual probabilities associated with group correspondences as output values for each test data point given by the calibrated SVM. Notably, they had complementary values (i.e., the probability of one group is equal to 1 minus the probability of the other in the classification between two diagnostics), and they were directly associated with the output category (i.e., the final classification was the one with probability >0.5). We conventionally set two levels of diagnosis confidence: an individual probability ≥ 0.8 (or ≤ 0.2) was considered to provide high diagnosis confidence, while probabilities between 0.2 and 0.8 were considered a "gray zone", with lower or insufficient diagnosis confidence for the clinical decision. Thus, we estimated the accuracy and the number of individuals with a high probability of being from the group for each classification.

Finally, we aimed to explore if NfL and 14-3-3 levels could help diagnose the individuals of the gray zone of the MRI diagnosis for the following comparisons due to the available data: AD vs. CTR, FTD vs. CTR, and AD vs. FTD. Thus, we created a reduced dataset with subjects having MRI data, NfL, and 14-3-3 levels. We trained and tested the proposed algorithm in 3 situations: MRI-based algorithm, CSF-based algorithm, and MRI and CSF-based algorithm to study if the individual probabilities towards the actual class increased. We did not include Aβ42, t-tau, and p-tau levels to avoid circularity, as these markers were used in the clinical diagnosis according to current criteria.

We implemented the ML algorithm in Python version 3.10.6 (www.python.org) with the Scikit-learn library [39].

3. RESULTS

3.1. Sample demographics

The prospective study includes 491 subjects: 215 AD, 103 FTD (56 bvFTD, 24 svPPA, 21 nfvPPA, and 2 PPA), and 173 cognitively normal control (CTR) participants. A subset of the study participants had CSF measures available: NfL (N=365) and 14-3-3 (N=182). Table 1 shows demographic information, group statistics, and biomarker levels. As expected, CSF biomarkers levels showed significant differences between groups (corrected p-value<0.05). There were differences in age and sex. As expected, based on previous studies, AD and CTR groups had more women than men; meanwhile, the FTD groups were more harmonized. Regarding age, healthy controls were younger than AD and FTD participants.

3.2. MRI-based probabilistic classification algorithm

We estimated the accuracy performance of our algorithm as the mean accuracy obtained in each k-fold of the test data. We got an accuracy of 88 ± 8% when discriminating AD patients from CTR, and 87 ± 4% when determining FTD patients from CTR. When we tried classifying AD vs. FTD patients, the accuracy was 82 ± 6%. Finally, we obtained an accuracy of 77 ± 6% when discriminating between the three groups (AD vs. FTD vs. CTR) (Table 2).

As can be seen in Figure 1, the resulting algorithms were well-calibrated, which allowed us to create confidence ranges in the algorithm classification. The comparison of AD vs. CTR showed that 73% of AD participants and 65% of CTR participants presented a probability higher than 0.8. In the FTD vs. CTR comparison, we found 74% FTD participants and 73% CTR participants with a probability ≥ 0.8. Finally, when discriminating AD vs. FTD, we found 73% AD participants and 74% FTD participants with probabilities above 0.8 for being classified as AD or FTD, respectively. Figure 2 shows the density of the individual probabilities and how the distribution between the clinical and the algorithm diagnosis is distributed within the group with an individual probability ≥ 0.8. Notably, the algorithm diagnosis and the clinical algorithm did not always coincide, also inside the higher probability of 0.8 (high confidence).

Then, we aimed to study the FTD clinical subtypes separately. Due to limitations in sample size, we merged svPPA and nfvPPA in the same group-PPA. We obtained 91 ± 2% accuracy for classifying bvFTD patients vs. CTR and 93 ± 4% when discriminating PPA patients from CTR. In both cases, the accuracy increased compared to the accuracy reported for all FTD together (87 ± 4%). Compared with AD, we obtained 85 ± 3% for the bvFTD vs. AD comparison and 91 ± 3% for the PPA vs AD. Finally, we obtained an accuracy of 68 ± 6% discriminating bvFTD from PPA.

3.3. Important MRI regions for classification

Figure 3 shows the region weights associated with each comparison. In summary, when comparing AD versus CTR, the GM volume of the hippocampus, putamen, and amygdala played the most crucial role. For FTD vs. CTR, we found that occipital, parietal, and frontal regions emerged as the top regions for the classification. Finally, when discriminating both dementias (AD vs. FTD), we found a widespread pattern in which the CTh measures were generally more important than subcortical GM volumes, especially those in the frontal lobe.

The results of the most crucial regions in the classifications considering bvFTD and PPA participants are shown in Figure 4. When discriminating bvFTD from CTR, the frontal and temporal lobes and the GM volume of the ventricles were the most important areas. In contrast, when differentiating between CTR and PPA participants, the top regions were GM volumes of the hippocampus, amygdala, and temporal lobe. When discriminating AD from bvFTD, the most important areas were the temporal, parietal, and occipital lobes. The frontal, parietal, and occipital lobes emerged in the PPA vs. AD discrimination. Finally, when discriminating bvFTD vs. PPA, the regions which contributed the most were the frontal, temporal, and occipital lobes.

3.4. Individual probabilities using MRI and CSF data

The group classification performance of the algorithm and the percentage of participants with an individual probability≥80% using MRI-only, CSF-only, and combined MRI and CSF data are presented in Table 2. Adding NfL and 14-3-3 data to the MRI data did not improve the results. However, some conclusions could be derived from the results.

For comparing AD vs. CTR, adding CSF data to the MRI did not increase the classification rate (Table 2, Figure 5). However, CSF data (NfL and 14-3-3) alone was enough to discriminate between AD and CTR participants.

Contrarily, in the comparison between FTD and CTR having MRI and CSF, more participants were classified with high confidence, with a probability ≥ 0.8 (see Table 2 and Figure 5). The accuracy with only CSF data and that of MRI + CSF data was very similar, 87 ± 8% and 86 ± 9%, respectively; however, when adding CSF data, CTR subjects with a CTR-probability higher than 0.8 increased from 23% to 53%. Thus, in this case, combining the MRI and CSF data reduced the participants in the gray zone of the diagnosis.

Finally, when we compared AD and FTD participants, combining MRI and CSF data increased both the accuracy and the number of subjects with a probability≥ 0.8 (see Table 2 and Figure 5).

4. DISCUSSION

In this study, we implemented a machine learning algorithm that discriminates FTD and AD subjects using data from structural MRI. In addition, our algorithm was able to differentiate subtypes of FTD with good accuracy. Clinical diagnosis requires decisions at the individual level, and the degree of confidence in the diagnosis is key in managing the patient. We approach the clinical question of diagnosis confidence using individual probabilities. Among our key results, we found that 74% FTD and 73% AD participants showed an individual probability≥0.8 of being well-classified by the algorithm in the FTD vs. AD comparison. Adding CSF neurodegeneration markers (NfL and 14-3-3) levels did not significantly improve the diagnosis classification or the number of patients with high individual probability for the diagnosis.

Previous ML algorithms using structural MRI data have reported accuracies between 76 and 97% for AD vs. CTR, 72-88% for FTD versus CTR, 51-90% for AD versus FTD, and 54-70% in discriminating between AD, FTD, and CTR [7, 11, 18, 21, 22, 40–47]. These studies used different algorithms, with the SVM being the most common.

We obtained accuracies that are in accordance with, or even outperformed, previously reported algorithms, especially for AD vs. FTD [16, 17, 48–50]. We have differentiated FTD expressions (bvFTD and PPA) against AD or CTR, outperforming previously published works [11, 21, 46]. First, regarding the comparisons with CTR, for bvFTD, we obtained a 91% accuracy, and in the case of the PPA participants, an accuracy of 93%. When classifying bvFTD and PPA separately against AD, we obtained accuracies up to 90% for both cases. However, when we tried to classify bvFTD vs. PPA, we obtained an accuracy of 68%, which is lower than the accuracy reported by Kim et al. [41], probably due to differences in the algorithm.

We depicted the patterns that drive accuracy for each classification setting, to obtain a comprehensive explanation of structural changes in both dementias. The GM volume of the hippocampus, putamen, and amygdala were essential in differentiating AD from CTR. By contrast, when differentiating FTD from CTR, the cortical regions were the most important, especially the CTh of occipital, parietal, and frontal regions. According to this, GM volumes of subcortical areas could help to identify AD patients, and the thickness of the cortex could be the key to identify FTD participants. This is in agreement with findings obtained with more classical analysis methods [12, 51–57]. Finally, regarding the FTD variants, frontal brain regions emerged for the bvFTD, and hippocampus and temporal regions were the most important in PPA, as reported before [51].

Besides reaching good accuracies, one of the main novelties of our work is that we obtained the individual probabilities for each diagnosis in all comparisons. Notably, as we built our first set of algorithms uniquely with MRI data, these probabilities might reflect each individual's brain atrophy severity. Using these values, we could identify the participants with high diagnosis confidence (with a probability upper to 80%) and those who do not have that high confidence that could be a candidate for further evaluations. Notably, more than 70% of AD and FTD participants were classified with high diagnosis confidence in the FTD vs. AD comparison.

Other studies using multimodal information also reported high classification accuracy combining data from different imaging modalities or other biological and clinical measures [24, 40, 49, 58]. Even so, in some cases, our scores with only structural MRI data showed better accuracy [18, 46, 59, 60]. Here, we evaluated if adding CSF data to

the MRI could improve the accuracy or the number of participants with a high diagnosis confidence. In our cohort, adding NfL and 14-3-3 CSF data to the MRI data provided low benefit for the accuracy of the group classification or the number of participants with high individual diagnosis probability. The fact that both, NfL and 14-3-3 levels and MRI data reflect neurodegeneration and no other aspects of the pathophysiological processes in these diseases could explain the lack of improvement by adding CSF data. We did not use Aβ42, t-tau, and p-tau to avoid circularity, as they were used for the AD clinical diagnosis.

Overall, our study has several strengths. First, its good performance makes it suitable for potential implementation in a clinical setting, especially in doubtful cases or locations with limited access to expert opinion or additional biomarkers. The key to individual probabilities thanks to the calibrated algorithm, also might represent a step toward personalized medicine. In addition, at the level of explainable ML, we identified the most critical regions for classification, contributing to the definition of structural atrophy patterns, and may be used for identifying target regions in further studies.

Our study also presents several limitations. First, it is unicentric. It has the advantage that all the participants had the same MRI scanner protocol and clinical criteria for the diagnosis. In the case of using the algorithm in other centers, the increased heterogeneity of the data could worsen the algorithm's performance. Another limitation regarding the FTD participants is that, when looking at the different clinical expressions, we reduced the sample size to approximately 50 participants for each group, and svPPA and nfvPPA had to be studied together. This means that the results are subject to large sampling variability. Future studies could further explore the subanalyses with the FTD phenotype subtypes in more detail. Finally, only some participants had NfL and 14-3-3 data available, and the smaller sample size might have impacted the results.

In conclusion, the proposed diagnosis algorithm has shown high accuracy classification scores with structural MRI data to discriminate AD, FTD, and CTR. This approach also provided individual MRI-based classification probability scores as an ancillary tool for studying the overlapping results between FTD and AD and a surrogate estimation for the confidence in the ML diagnosis.

ABSTRACT

Introduction: Frontotemporal dementia (FTD) patients usually show more asymmetric atrophy patterns than Alzheimer's Disease (AD). Here, we define the individual Cortical Asymmetry Index (CAI) and explore its diagnostic utility.

Methods: We collected structural T1-MRI scans from 554 participants, including FTD (all variants), AD, and healthy controls, and processed them using Freesurfer. We defined the CAI using measures based on a metric derived from information theory with the cortical thickness measures. A subset of the study participants had additional follow-up MRIs, cerebrospinal fluid (CSF), or plasma measures. We analyzed differences at cross-sectional and longitudinal levels. We then clustered FTD and AD subjects based on the CAI values and studied the fluid biomarkers characteristics within each cluster.

Results: CAI differentiated FTD, AD, and healthy controls. It also distinguished the semantic variant Primary Progressive Aphasia (svPPA) from the other FTD phenotypes. In FTD, the CAI increased over time. The cluster analysis identified two subgroups within FTD, characterized by different CSF and plasma neurofilament-light (NfL) levels, and two subgroups within AD, with different plasma Glial fibrillary acidic protein (GFAP) levels. In AD, CAI correlated with plasma-GFAP and Mini-Mental State Examination (MMSE); in FTD, the CAI was associated with NfL levels (CSF and plasma).

Conclusions: The method proposed here for the CAI at the individual level could quantify asymmetries previously described visually. The CAI could define clinically and biologically meaningful disease subgroups.

1. INTRODUCTION

Frontotemporal dementia (FTD) is a clinically, pathologically, and genetically heterogeneous neurodegenerative disorder associated with frontal and temporal atrophy. FTD patients tend to be misdiagnosed with Alzheimer's Disease (AD), especially at relatively young ages, although early behavioral and personality changes typical of FTD are not common in initial AD (Harris et al., 2015; Koedam et al., 2010; Mendez et al., 2013). However, AD is the most frequent dementia and sometimes is the first choice for many non-specialist clinicians. For this reason, there is a need to identify tools to help accurately diagnose dementia's underlying etiologies and their subtypes. Cortical asymmetry has been associated with characteristically clinical features in psychiatric and neurological conditions (Kong et al., 2018; Toga and Thompson, 2003). In this sense, compared with AD, FTD subjects show a more asymmetrical pattern at visual inspection (Gordon et al., 2016; Rabinovici and Miller, 2010; Seelaar et al., 2011; Whitwell, 2019).

Within the FTD phenotypes, the semantic variant of Primary Progressive Aphasia (svPPA) is the most asymmetric (Gordon et al., 2016; Rohrer and Rosen, 2013; Thompson et al., 2003). In this sense, the study of brain asymmetry could help in the diagnosis of the different phenotypes of FTD: behavioral variant frontotemporal dementia (bvFTD) or FTD-related primary progressive aphasia (PPA) phenotypes, including svPPA and Nonfluent Variant Primary Progressive Aphasia (nfvPPA) (Gorno-Tempini et al., 2011; Rascovsky et al., 2011). A measure of cortical asymmetry could help in the early differential diagnosis or monitoring the progress of neurodegeneration (Herzog and Magoulas, 2021; Toga and Thompson, 2003).

The differences between measures from the left and right hemispheres can be detected in the structural magnetic resonance imaging (MRI) (Guadalupe et al., 2017; Kong et al., 2018; Toga and Thompson, 2003). There is no established way to calculate the asymmetry, and different approaches have been used in multiple works on various brain diseases (Douglas et al., 2018; Herzog and Magoulas, 2021; Kalavathi et al., 2017; Kong et al., 2020; Maingault et al., 2016; Sarica et al., 2018; Schijven et al., 2023).

Then, computational algorithms can obtain measures of cortical asymmetry from the global and regional cortical thickness (CTh), surface area, or subcortical volumes. The most common method estimates the asymmetry as (L-R)/[(L+R)/2], being L for the left hemisphere measure and R for the right hemisphere measure. However, previously published works indicate that approaches using the probability distribution to obtain an asymmetric index could get better results and are currently being used in other biological areas (Estrada et al., 2022; Newton et al., 2014; Ramakrishnan and Bose, 2017).

In this study, first, we defined the Cortical Asymmetry Index (CAI) using measures derived from the information theory with CTh measures. Secondly, we aimed to study if the CAI might help in the differential diagnosis of FTD vs. AD and if it had a differential effect across the FTD clinical expressions. Then, we wanted to study cortical asymmetry changes at the longitudinal level. Finally, we explored the capability of the CAI to identify subgroups and its correlation with fluid biomarkers and cognitive measures.

2. METHODS

2.1. Participants

Participants were recruited from the Alzheimer's disease and other cognitive disorders unit of the Hospital Clínic de Barcelona (HCB), Barcelona, Spain. All participants underwent a complete clinical and cognitive evaluation and a 3T high-resolution structural MRI scan. A subset of the study participants had available follow-up visits, cerebrospinal fluid (CSF), or plasma measures.

All AD participants fulfilled the criteria for mild cognitive impairment due to AD or mild dementia due to AD (Albert et al., 2011; McKhann et al., 2011) supported by the CSF biomarkers results according to the National Institute on Aging/Alzheimer's Association Research Framework 2018 (Jack et al., 2018). We included amnesic and non-amnesic participants in the study. The FTD participants fulfilled the diagnostic criteria for bvFTD, svPPA, or nfvPPA (Gorno-Tempini et al., 2011; Rascovsky et al., 2011).

The study was approved by the HCB Ethics Committee (HCB 2019/0105), and all the participants signed the informed consent.

2.2 Biochemical markers

We used commercially available single-analyte enzyme-linked immunosorbent assay (ELISA) kits to determine levels of CSF neurofilament-light chain (NfL) (IBL International, Hamburg, Germany) and CSF 14-3-3 (CircuLex, MBL International Corporation, Woburn, MA) at the Alzheimer's disease and other cognitive disorders group laboratory, Barcelona, Spain.

Plasma biomarkers concentrations were measured using single molecule array (SIMOA), Quanterix Neurology 4-Plex A including total tau (t-tau), glial fibrillary acidic protein (GFAP), NfL, and Ubiquitin C-terminal hydrolase L1 (UCH-L1) and the Quanterix p-tau181 Advantage V2 and V2.1 assays following the manufacturer's protocol (Quanterix, Billerica, MA), we harmonized the values of the two kits.

2.3 MRI acquisition

We acquired a high-resolution 3D structural dataset (T1-weighted, MP-RAGE, repetition time = 2.300 ms, echo time = 2.98 ms, 240 slices, field-of-view = 256 mm, voxel size = 1 × 1 × 1 mm) for everyone at each time point in a 3T Magnetom Trio Tim scanner (Siemens Medical Systems, Germany) upgraded to a 3T Prisma scanner (Siemens Medical Systems, Germany) during the study.

2.4 MRI processing

We used the processing stream available in FreeSurfer version 6.0 (http://surfer.nmr.mgh.harvard.edu.sire.ub.edu/) to perform cortical reconstruction and volumetric segmentation of the T1-weighted acquisitions. FreeSurfer allowed us to generate automated CTh maps; steps are reported in detail elsewhere (Fischl et al., 2004; Fischl and Dale, 2000). This study used the mean CTh measures in 68 cortical

parcellations (34 per hemisphere) derived from atlases available in FreeSurfer (Desikan et al., 2006). All images and individual segmentations were visually inspected and manually corrected if needed.

2.5 Cortical Asymmetry Index (CAI)

We obtained the CAI by calculating the Jensen-Shannon distance (JSD), a methodology based on a metric derived from information theory (Lin, 1991). The JSD measures the difference between two probability distributions (P1 and P2) using the square root of the Jensen-Shannon divergence, which is based on the Kullback-Leibler divergence (KLD). The KLD is also referred to as relative entropy between two distributions. It is calculated as the negative sum of the probability of each event in P1 multiplied by the logarithm of the probability of the same event in P2 divided by the probability of the event in P1. The JSD is the symmetric and normalized version of KLD, so the JSD from one probability P1 to another probability P2 is the same as the JSD of P2 from P1. We obtained the CAI using the distribution of CTh measures of each brain hemisphere (previously obtained with the software FreeSurfer) that represents the difference in CTh distribution between brain hemispheres. Thus, the CAI allows us to quantify brain structural asymmetry at the individual level. CAI is a non-dimensional measure with higher values indicating a more asymmetric brain.

The CAI was calculated using in-house methods implemented in Python version 3.10.6 (www.python.org).

2.6 Statistical Analysis

We first compared the CAI between all groups, including healthy controls, AD, and FTD patients. Then, we performed comparisons across the different FTD phenotypes. In both cases, we used the ANOVA test, corrected by age when needed, and a post hoc analysis with the Tukey test to assess multiple comparisons. Finally, we performed longitudinal analyses with Linear Mixed Effects Models (LME) to study changes between visits; we added age at MRI, sex, and age of onset (for AD and FTD) as fixed effects.

We then analyzed the CAI using cluster analyses for FTD and AD participants separately to evaluate whether subgroups emerged within each disease. We used hierarchical clustering, precisely agglomerative nesting cluster with Ward's method and Manhattan metric. We determined the optimal number of clusters in each case with the Silhouette strategy. Then, with the cluster groups obtained, we studied differences in fluid biomarkers across subgroups with non-parametric tests such as the Kruskal Wallis or Wilcoxon tests. All biomarkers' levels were converted to z-score before these calculations.

Finally, we evaluated the association between CAI and the CSF and plasma biomarkers that emerged in the cluster analysis. In addition, we studied the correlation of CAI with age and Mini-Mental State Examination (MMSE). We used Spearman's rank correlation coefficient due to the limited samples.

We implemented the statistical analysis and the cluster analysis (with cluster and factoextra packages) in R version 4.2.1

3. RESULTS

3.1. Demographics

We included 554 participants: 230 AD (30 with follow-up MRI scans with two years approximately between scans), 101 FTD (30 with follow-up MRI scans with one year and a half approximately between scans), and 173 healthy controls (96 with follow-up MRI scans with two years approximately between scans). The 101 FTD participants were distributed as follows: 55 bvFTD (14 follow-up MRI scans), 21 nfvPPA (7 follow-up MRI scans), and 24 svPPA (9 follow-up MRI scans). AD participants were 64% women, and the mean age was 65.3 ± 9.7; FTD participants were 48% women, the mean age was 63.7 ± 8.4, and healthy control participants were 61% women, and the mean age was 59.4 ± 15.0. Healthy controls were younger than AD and FTD participants ($p<0.05$). As expected, CSF and plasma biomarkers levels showed significant differences between groups, except for plasma t-tau and UCH-L1 (Table 1).

3.2. Cross-sectional CAI differences

AD participants had a CAI of 0.40 ± 0.28, FTD participants 0.59 ± 0.52, and healthy controls 0.16 ± 0.10. We found higher CAI in AD and FTD patients than healthy controls (adjusted p-value < 0.0001), meaning a more asymmetric brain structure. FTD participants also presented a higher CAI than AD patients (adjusted p-value<0.0001) (Figure 1).

Then, we studied the CAI across FTD clinical phenotypes. The bvFTD patients had a mean CAI of 0.46 ± 0.46, nfvPPA patients 0.62 ± 0.62, and svPPA patients 0.83 ± 0.48. When studying the differences between FTD clinical phenotypes, svPPA presented higher CAI values than bvFTD (adjusted p-value<0.01) (Figure 2).

3.3. Longitudinal changes in CAI

The mean CAI for the follow-up visits was 0.42 ± 0.31 for AD patients, 0.80 ± 0.77 for FTD patients, and 0.16 ± 0.12 for healthy controls. At the longitudinal level (Figure 3), we found that CAI significantly increased in FTD, indicating a significantly more asymmetric brain over time (p-value=0.012 between baseline and follow-up, measured as the interaction with age). We did not find changes between visits in AD patients and healthy controls.

3.4. Cluster Group

The cluster analysis was used to identify subgroups based on their CAI. Then, we compared biomarker values between clusters. This method could divide the FTD group into Cluster 1 (N=41) and Cluster 2 (N=58). Cluster 1 presented a more asymmetric brain with 62.5% svPPA, 35.2% bvFTD, and 33.3% nfvPPA of the total cohort participants. In contrast, Cluster 2 showed a less asymmetric brain and grouped as 37.5% svPPA, 64.8% bvFTD, and 66.7% nfvPPA of the total cohort participants. CSF and plasma levels of NfL were increased in Cluster 1 compared to Cluster 2 (p-value=0.0059 and p-value=0.042, respectively) (Figure 4a).

Within AD participants, the cluster analysis also yielded two groups, presenting differences in plasma GFAP levels (p-value=0.035) (Figure 4b). Then, we tried to find an explanation based on the clinical profile to explain the clusters. However, we did not

find any difference between clusters at a clinical level. The distribution of the participants in the two clusters was not grouped due to sex, age of onset (early-onset AD vs. late-onset AD), age of disease duration, AD phenotypes (amnesic vs. non-amnesic), MMSE, APOE status, or the combination of these variables.

3.5. Relation between CAI, fluid biomarkers, and global cognition measures

We assessed whether CAI values correlated with the levels of the fluid biomarkers that emerged in the cluster analysis, in addition to MMSE and age (Figure 5). We found a weak positive correlation in AD for plasma-GFAP ($r = 0.20$, p-value < 0.05) and a weak negative correlation with MMSE ($r = -0.26$, p-value < 0.001). For FTD patients, we found a significant positive correlation of CAI values with NfL levels; both CSF-NfL ($r = 0.27$, p-value < 0.05) and plasma-NfL ($r = 0.41$, p-value < 0.05). We found no correlation between CAI and fluid biomarkers in the different FTD clinical phenotypes. Healthy controls did not present any correlation between the CAI and age either. Age did not correlate with CAI in any of the groups.

4. DISCUSSION

In this study, we propose a methodology to estimate the brain structural asymmetries, namely the CAI, for neurodegenerative diseases, especially FTD and AD. We used an information theory method to calculate each individual's CAI. CAI mean values differentiate healthy controls from dementia participants, and FTD from AD, and between FTD phenotypes. We studied the brain asymmetries over time and found an increase in asymmetry for FTD. Cluster analysis using the CAI values for both FTD and AD enabled us to identify disease subgroups and study the relationship between brain asymmetry and the levels of fluid biomarkers.

Our first finding, the increased asymmetry for FTD, aligns with what has been described in the literature using a mix of non-standardized measures and visual inspection. The svPPA is the most asymmetrical clinical phenotype of FTD, usually showing greater left than right atrophy of the temporal lobes (Bruun et al., 2019;

Gordon et al., 2016; Gorno-Tempini et al., 2011, 2004; Mesulam et al., 2014; Rohrer and Rosen, 2013; Schroeter et al., 2007; Seelaar et al., 2011; Whitwell et al., 2015). Also, in agreement with our findings, the FTD brain asymmetry has been reported to increase over time (Rohrer and Rosen, 2013; Whitwell et al., 2015). In contrast, AD is commonly described as symmetric dementia: the atrophy presented in one hemisphere of the brain, usually, is similar in the other. However, some studies reported asymmetric patterns in AD (Derflinger et al., 2011; Low et al., 2019; Mesulam et al., 2014; Roe et al., 2021; Rombouts et al., 2000). In our study, AD patients present lower CAI when compared with FTD patients, meaning less asymmetry. However, if compared to healthy controls, they present an asymmetrical brain.

Previous works studying brain asymmetries in FTD and AD usually report these asymmetries at the visual level. Still, further studies are needed that present a methodology to evaluate and quantify this phenomenon systematically. Although some studies have been done to quantify asymmetries (Boccardi et al., 2002; Bocchetta et al., 2018; Bruun et al., 2019; Low et al., 2019; Schroeter et al., 2007), we chose a more complex methodology based on information theory to obtain the estimation of an asymmetric index. For this reason, we proposed to estimate the asymmetric index with the JSD measure. This novel measure based on entropy has recently been used to study similarities in different biological and clinical areas. For example, it has been used to help in the detection of ischemic stroke, to study long-term surgical outcomes in the brain for epilepsy patients, to study cancer cells to find link cells with near-identical gene expression, or to study the individual metabolic network in patients with type 2 diabetes (Estrada et al., 2022; La Manno et al., 2021; Li et al., 2022; Zhu et al., 2022). We demonstrated that the CAI defined here could be of help for the differentiation of the clinical expressions or dementias, to study the progression of the disease, or to identify subgroups.

Other studies have explored quantification strategies for brain symmetries to differentiate between different dementias successfully (Bruun et al., 2019; Kitagaki et al., 1998). However, there is currently no standard and accurate methodology for this, and the CAI presented here showed promising results. Also, it was helpful in identifying FTD clinical phenotypes. For example, svPPA presented different levels compared to bvFTD. We found that the svPPA is the most asymmetric clinical expression of FTD,

which is in accordance with previous literature, using visual scales (Seelaar et al., 2011; Whitwell, 2019). We replicated the previous results in this study and quantified these differences using the CAI.

Our cluster analysis yielded FTD and AD participants into two subgroups according to their asymmetry indexes. As cluster analysis is a no supervised statistical approach, we aimed to find an explanation using clinical and biomarker data. Among the two subgroups for FTD patients, the more asymmetric cluster was enriched with svPPA participants and the other cluster with nfvPPA and bvFTD. The cluster analysis was in accordance with the differences studied between FTD clinical phenotypes using ANOVAs, where we found a significant difference between svPPA and bvFTD. Overall, we observed that svPPA presented the highest CAI compared to nfvPPA and bvFTD. AD participants were also subdivided into two subgroups; however, we could not find an explanation based on the clinical profile of the subjects. We analyzed its association with fluid biomarkers to study further implications of cortical brain asymmetry. We found that in the FTD Cluster 1, CAI values were associated with higher levels of NfL in both CSF and plasma with respect to the bvFTD and nfvPPA and that higher CAI predicted higher NfL (CSF and plasma) in FTD patients. This suggests that NfL (CSF and plasma) is directly associated with brain asymmetry. Previous studies reported that NfL levels in CSF and plasma were associated with brain atrophy (Illán-Gala et al., 2021; Meeter et al., 2016; Rohrer et al., 2016). However, the association between NfL and brain asymmetries was not investigated. When studying AD, we found that different CAI groups were associated with plasma GFAP levels. The AD-less asymmetric cluster presented higher GFAP levels. This biomarker has been previously associated with brain atrophy due to aging or disease severity (Ebenau et al., 2022; Traub et al., 2022). However, its association with brain asymmetry has not been studied before. Then, we examined the correlation between GFAP levels and CAI in AD patients and obtained a positive correlation. Overall, these associations between brain asymmetries and fluid biomarkers suggest that both contribute to defining AD subgroups.

Finally, FTD participants presented higher levels of brain asymmetry over time, suggesting that the CAI could indicate FTD progression. Previous studies have shown that FTD's different genetic or clinical expressions behave differently in becoming more

asymmetric over follow-up visits (Mahoney et al., 2012; Meeter et al., 2017; Whitwell et al., 2012). Regarding AD, no differences in CAI over time were found for AD patients.

In conclusion, the proposed CAI measure might identify differences between AD and FTD and between FTD phenotypes. It might be a sensitive measure to determine the disease progression of the FTD participants. Cortical asymmetry drives subgrouping inside FTD and AD, associated with various fluid biomarker levels. Overall, this highlights the potential relevance of quantifying cortical asymmetry. Further studies deepening into the genetic expressions of FTD or investigating the predictive value of the CAI towards clinical progression might be of interest.

Abstract

Background and objectives The *C9orf72* expansion is the most common genetic cause of frontotemporal dementia (FTD) and/or motor neuron disease (MND). Corticospinal degeneration has been described in post-mortem neuropathological studies in these patients, especially in those with MND. We used MRI to analyze white matter (WM) volumes in presymptomatic and symptomatic *C9orf72* expansion carriers and investigated whether its measure may be helpful in predicting the onset of symptoms.

Methods We studied 102 presymptomatic *C9orf72* mutation carriers, 52 symptomatic carriers: 42 suffering from FTD and 11 from MND, and 75 non-carriers from the Genetic Frontotemporal dementia Initiative (GENFI). All subjects underwent T1-MRI acquisition. We used FreeSurfer to estimate the volume proportion of WM in the brainstem regions (midbrain, pons, and medulla oblongata). We calculated group differences with ANOVA tests and performed linear and non-linear regressions to assess group-by-age interactions.

Results A reduced WM ratio was found in all brainstem subregions in symptomatic carriers compared to both noncarriers and pre-symptomatic carriers. Within symptomatic carriers, MND patients presented a lower ratio in pons and medulla oblongata compared with FTD patients. No differences were found between presymptomatic carriers and non-carriers. Clinical severity was negatively associated with the WM ratio. *C9orf72* carriers presented greater age-related WM loss than non-carriers, with MND patients showing significantly more atrophy in pons and medulla oblongata.

Discussion We find consistent brainstem WM loss in *C9orf72* symptomatic carriers with differences related to the clinical phenotype supporting the use of brainstem measures as neuroimaging biomarkers for disease tracking.

Keywords Frontotemporal dementia · *C9orf72* · GENFI · Brainstem

Introduction

Frontotemporal dementia (FTD) refers to a heterogeneous group of neurodegenerative disorders that mainly affects the frontal and temporal lobes of the brain producing behavioral and language impairment [1]. Amyotrophic lateral sclerosis (ALS) is the most frequent motor neuron disease. It is caused by the neurodegeneration of motor neurons and the corticospinal and corticobulbar tracts leading to progressive weakness and muscular atrophy [2]. Due to the scientific advances in the last decades, it is now recognized that

Agnès Pérez-Millan and Sergi Borrego-Écija have contributed equally.

FTD and ALS are part of a clinical, neuropathological, and genetic continuum [3–6].

Although frequency varies geographically, the pathological hexanucleotide expansion in the *chromosome 9 open reading frame 72* (*C9orf72)* gene is the most common genetic cause of FTD, and ALS [7, 8]. The *C9orf72* repeat expansion is inherited with an autosomal dominant pattern with almost full penetrance leading to disease onset at a mean age of 58 years, although a wide range of age of onset (20–90 s) has been described [9]. The correlation between parental age at onset and individual age at onset for *C9orf72* expansion carriers is weak ($r=0.32$), and thus, not useful for individual predictions [9]. In the same way, whether the symptom onset would appear in form of FTD, or ALS remains unpredictable. However, future disease-modifying drugs might be useful for both clinical phenotypes and treatments might be more useful when used in early or even presymptomatic phases of the disease. For that reason, there is a need for biomarkers that are able to provide information about the proximity of onset and track disease progression in both phenotypes. In this sense, cohorts of mutation carriers, such as the genetic frontotemporal initiative (GENFI), provide the opportunity to study the first stages of the disease and to identify markers of symptom onset and progression [10].

Previous studies have described structural changes in presymptomatic FTD subjects using brain MRI [11–15]. Concerning *C9orf72* carriers, previous studies have shown presymptomatic brain changes in the thalamus, cerebellum, hippocampus, amygdala, and hypothalamus [16, 17]. Most of these studies have focused on grey matter. In contrast, white matter (WM) degeneration has received comparatively less attention but demonstrates early and widespread WM integrity loss in *C9orf72* carriers [18].

The neuropathological examination of ALS patients reveals loss of motor neurons and the consequent degeneration of the corticospinal and corticobulbar tracts [19, 20]. This degeneration leads to lateral sclerosis of the spinal cord which gives the name to the disease. In addition to spinal cord changes, ALS patients also present relevant atrophy of the white matter areas that contain the corticospinal and corticobulbar tracts at the brainstem, especially the pyramids in the medulla oblongata. Previous work has demonstrated that changes in the spinal cord and brainstem in ALS can be detected in vivo using structural MRI [21, 22]. In a recent study, Querin et al. reported significant WM reduction in the spinal cord of presymptomatic *C9orf72* carriers using cervical cord MRI [23]. Assessing WM changes in the brainstem presents some potential benefits from cervical spinal cord evaluation, as the possibility of being measured with other brain changes in the brain MRI.

In this work, we investigate the utility of brainstem WM loss as a biomarker for *C9orf72* patients. We hypothesize that symptomatic *C9orf72* carriers would present more WM loss in the brainstem compared to non-carriers, especially in those patients with motor neuron symptoms. We also aim to study whether WM loss is identifiable in presymptomatic *C9orf72* carriers.

Materials and methods

Participants

Two hundred thirty five participants' data were obtained from the data freeze 4 (DF4) of the GENFI, an international multicenter study of known carriers of a pathogenic mutation or at risk of carrying a mutation because a first-degree relative was a known symptomatic carrier [11]. Symptomatic subjects were FTD or ALS patients carrying the *C9orf72* pathogenic expansion. Presymptomatic and noncarriers subjects were all first-degree relatives of *C9orf72* mutation carriers who consent to be tested for their genetic status.

All participants' imaging data were acquired at each time point using 3 T on scanners from three different manufacturers: Philips Healthcare (Koninklijke Philips NV, Amsterdam, Netherlands), GE Healthcare Life Sciences (General Electric, Boston, MA, USA) and Siemens Healthcare Diagnostics (Siemens, Erlangen, Germany). Protocols were designed to harmonize across scanners and sites as much as possible [11]. Subjects were classified into four groups according to their genetic status (carriers or non-carriers) and their clinical diagnosis as follows: (a) non-carriers; (b) presymptomatic *C9orf72* carriers if no diagnostic criteria were fulfilled, (c) symptomatic *C9orf72* carriers with FTD presentations in the form of behavioral variant FTD [24] or primary progressive aphasia [25] and (d) symptomatic *C9orf72* carriers with MND presentation in form of ALS or ALS-FTD [26, 27]. The disease stage of all participants was scored following the global and sum of boxes Clinical Dementia Rating adapted to FTD patients (CDR®+NACC-FTLD) rating scale [28]. The severity of motor neuron symptoms was scored with the ALS Functional Rating Scale-Revised (ALSFRS-R), a validated rating instrument for monitoring the progression of disability in ALS patients [29]. The ALSFRS-R obtains a final index of disability by scoring 12 different motor and respiratory items from 4 (no disability) to 0 (marked disability). Written informed consent was obtained from all participants. All procedures were approved by local ethics committees at each site.

MRI acquisition and processing

Participants underwent a 1.1-mm isotropic resolution volumetric T1 MRI imaging on a 3T scan using the sequences defined within the GENFI consortium. Nineteen scanners were used across different sites. MRIs of all subjects were downloaded from GENFI database and processed using

FreeSurfer version 6.0 (http://surfer.nmr.mgh.harvard.edu/) in the same center.

After the standard FreeSurfer segmentation and parcellation [30–32], we used an additional FreeSurfer pipeline to segment the brainstem region and its three main structures (midbrain, pons, and medulla oblongata) [33]. Figure 1 represents the imaging methodology to obtain the brainstem region segmentation. We assessed the WM parcel for the brainstem structures by multiplying each of the regions by the WM mask. To remove the effect of brain size, we calculated the ratio of WM for each of its structures (midbrain, pons, and medulla oblongata) using the total volume of the corresponding region (region-WM volume/region-whole volume). All images were visually inspected and manually corrected when needed.

Statistical analysis

Differences in demographic data between groups were assessed using ANOVA test for continuous variables and Fisher test for dichotomous data. Post-hoc studies were assessed for both cases to identify the pair-wise group differences, using *T*-tests or Fisher test accordingly. Statistical significance was set at $p < 0.05$, with corrections for multiple comparisons using the Benjamini–Hochberg procedure.

We used ANOVA test to study group differences in the WM ratio for the brainstem subregions. Age at baseline, sex and scanner were used as covariates. Then, Tukey's HSD test was used to identify pairwise differences between groups with Benjamini–Hochberg corrections for multiple comparisons. We compared the non-carriers, the presymptomatic carriers, carriers with FTD, and carriers with MND with the same procedure. Differences in the WM ratio between CDR® + NACC-FTLD global stages were assessed using Kruskal–Wallis test for all carriers, while Spearman's rank correlation coefficient was used to study the relationship between the WM ratio and the CDR® + NACC-FTLD sum of boxes and the ALSFRS-R. We evaluated multiple linear and non-linear regressions (logarithmic, polynomial to the second, third and fourth order) to test the association between the WM ratio (dependent variable) and the genetic status, age, and their interaction. For these analyses we added scanner and sex as covariates. Models were compared using R^2 and the Akaike information criterion (AIC). R (https://www.r-project.org/) version 4.0.5 was used for all analyses.

Results

Demographic and clinical characteristics of participants

After the data quality assessment the sample was reduced to 229 participants due to the segmentation problems identified. The final sample used in the analyses included: 102 presymptomatic carriers, 52 symptomatic carriers (41 FTD and 11 ALS or ALS-FTD), and 75 non-carriers (Table 1). Some of the acquisitions ($N = 43$ subjects) had a limited Field of View, so it was not possible to measure the entire medulla oblongata ROI. Thus, these images were not included in the sub-analyses of this region (21 presymptomatic, 7 symptomatic, and 15 non-carriers).

We found significant differences between the four groups (non-carriers, presymptomatic, symptomatic-FTD, symptomatic-ALS) in sex and age. Both symptomatic groups were older than the non-carriers and presymptomatic groups ($p < 0.0001$). Therefore, these variables were included as covariates in all further analyses. No significant differences were found in any demographic or clinical variables between non-carriers and presymptomatic carriers (Table 1).

Group differences in brainstem WM ratio

Non-carriers showed WM ratios very close to 1 (0.96 for the midbrain, 0.99 for the pons, and 0.97 for the medulla). No differences were found in any region between the presymptomatic and the non-carrier groups. The *C9orf72* FTD group

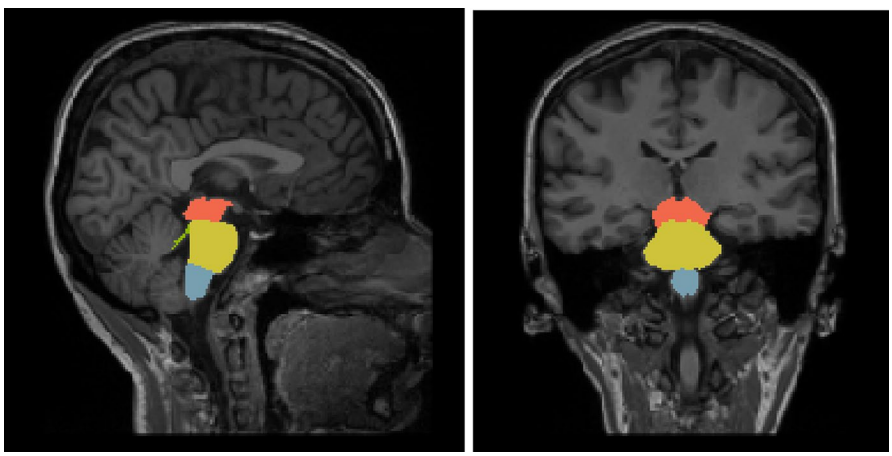

Fig. 1 The brainstem segmentation for all the matters for two different views. Orange represents the midbrain region, yellow represents the pons region and blue represents the medulla oblongata region. In this case, this subject is a healthy control

Table 1 Baseline demographics for controls, presymptomatic and both symptomatic carriers groups

	Non-carriers	*C9orf72* presymptomatic carriers	*C9orf72* FTD carriers	*C9orf72* MND carriers
Number of participants	75	102	41	11
Sex (f/m)	48/27	63/39	16/25*	4/7*
Age, years Mean (sd)	45.2 (12.6)	44.9 (11.8)	62.8 (8.4)**	62.6 (6.4)**
Age at onset, years Mean (sd)	–	–	57.2 (9.5)	59.5 (6.1)
EYO, years Mean (sd)	− 15.0 (11.6)	− 13.8 (11.9)	5.1 (6.1)**	1.4 (4.0)**
CDR®+NACC-FTLD Global Median (range)	–	–	2 (1–3)	2 (1–3)
CDR®+NACC-FTLD Sum of Boxes Median (range)	–	–	12.5 (1–22)	7.5 (1–18)

Brainstem subregions volumes and WM ratio. Show the group differences for the whole volume/WM ratio

EYO estimated years to onset, *FTD* frontotemporal dementia, *f* female, *m* male, *MND* motor neuron disease, *sd* standard deviation

*Statistical differences ($p < 0.05$) compared with non-carriers and presymptomatic carriers

**Statistical differences ($p < 0.0001$) compared with non-carriers and presymptomatic carriers

showed a lower WM ratio than non-carriers and presymptomatic carriers in all regions ($p < 0.01$ in the medulla, and $p < 0.0001$ in the midbrain and pons). The *C9orf72* MND group showed a lower WM ratio than the non-carriers and the presymptomatic carriers in all regions ($p < 0.0001$ in all comparisons). The MND group also showed a lower WM ratio than the FTD group in the medulla ($p < 0.0001$), and pons ($p < 0.0001$; (Fig. 2).

WM ratio across the severity of cognitive and motor symptoms

When studying the relationship between the WM ratio with the global CDR®+NACC-FTLD rating scale for all carriers subjects, we observed that higher clinical scores were significatively associated with lower WM ratios in all brainstem regions (Kruskal–Wallis $p < 0.001$ for all regions; Fig. 3A). Pairwise comparisons between CDR®+NACC-FTLD stages were performed for consecutive stages, depicting significant differences between the CDR = 0.5 and CDR = 1

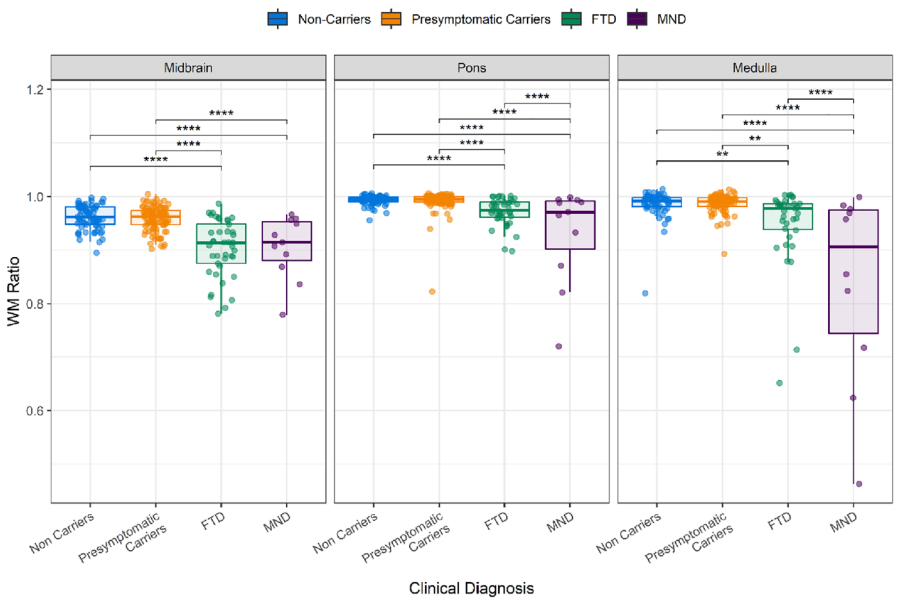

Fig. 2 Boxplot of the WM ratio volume of each brainstem region at baseline. Indicates *$p < 0.05$, **$p < 0.01$ and ***$p < 0.001$, ****$p < 0.0001$

stages in the midbrain ($p < 0.05$). Additionally, moderate significant negative correlations between the WM ratio and the CDR® + NACC FTLD sum of boxes were also found for all brainstem regions (midbrain $r = -0.57$, pons $r = -0.49$ and medulla oblongata $r = -0.45$; $p < 0.0001$ all; Fig. 3B).

To assess if the WM ratio was correlated to the severity of the motor neuron symptoms, we evaluate its relationship with the ALSFRS-R score in *C9or72* carriers (Fig. 3C). We found a weak negative correlation in pons ($r = -0.37$, $p < 0.05$), but a moderate negative correlation in midbrain ($r = -0.45$; $p < 0.001$) and medulla ($r = -0.46$, $p < 0.01$).

Brainstem WM ratio and age trajectories according to the genetic status

When comparing the relationship between the WM ratio and age, we found that carriers and non-carriers showed similar trajectories until the 6th decade of life. After this

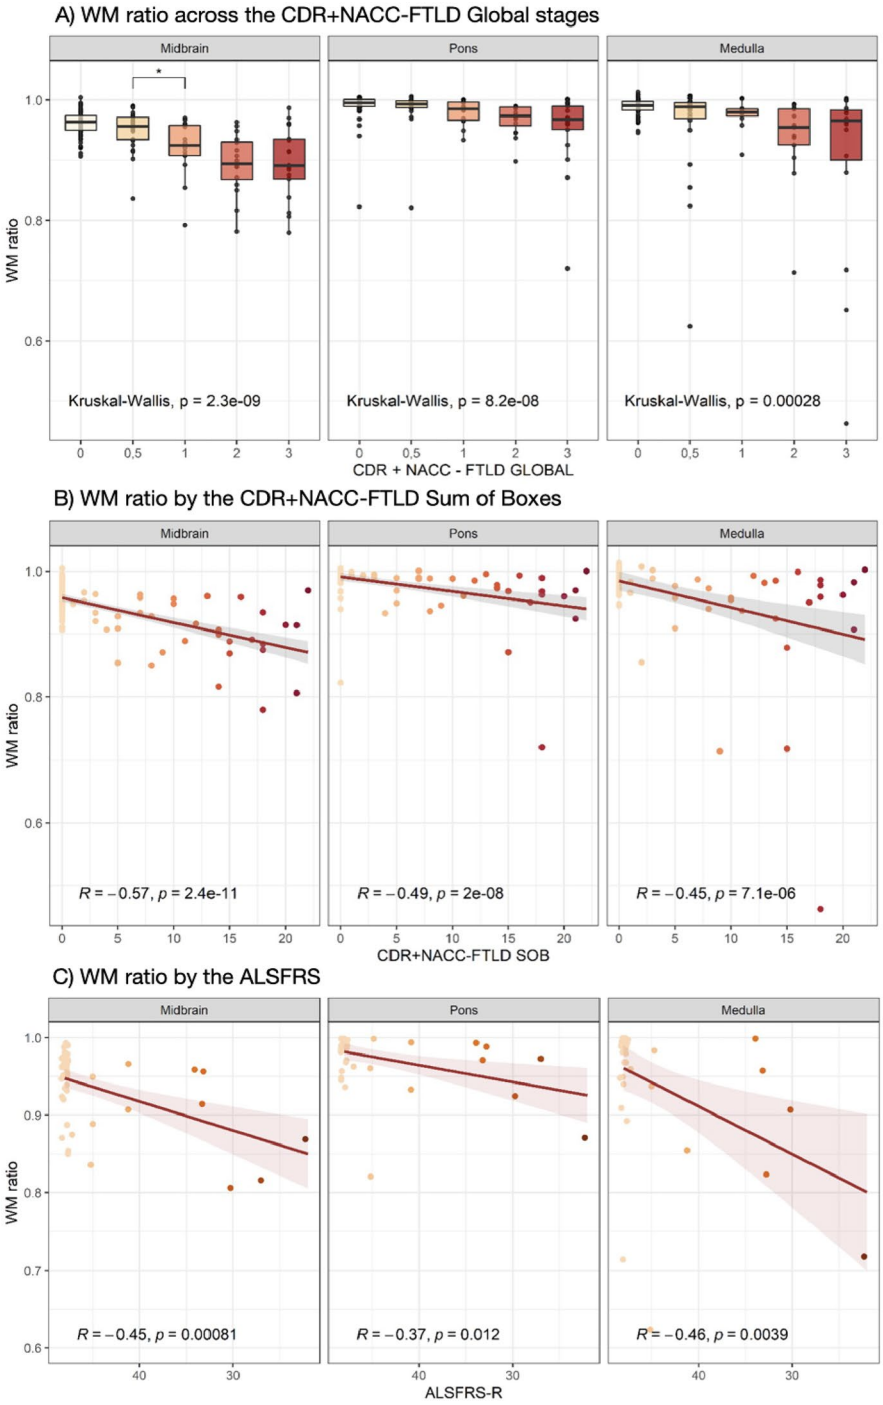

Fig. 3 **A** Boxplot of WM ratio across the *CDR® + NACC-FTLD* Global stages for the carriers' participants. Pairwise comparisons between stages were performed only for consecutive stages, finding significant differences between the 0.5 and the 1 stages in the midbrain: $*p < 0.05$, **B** Scatter plots of WM ratio by the *CDR® + NACC-FTLD* Sum Of Boxes. Red lines represent the correlation analyses, **C** Scatter plots of WM ratio by the ALSFRS-R in the different regions for the carriers' participants. Red lines represent the correlation analyses

age, carriers presented a greater loss of WM ratio than non-carriers, especially in the midbrain (Fig. 4A). The multiple linear regression comparing carriers and non-carriers showed similar results (Table 2). For both groups, age was related to lower WM ratios in the midbrain ($p < 0.001$). Carriers showed a greater loss of WM ratio by age than non-carriers in the midbrain ($p < 0.05$), suggesting a further loss of WM due to neurodegeneration. No other statistical differences were found between carriers and non-carriers. Due to the distribution of the trajectories, we also explored

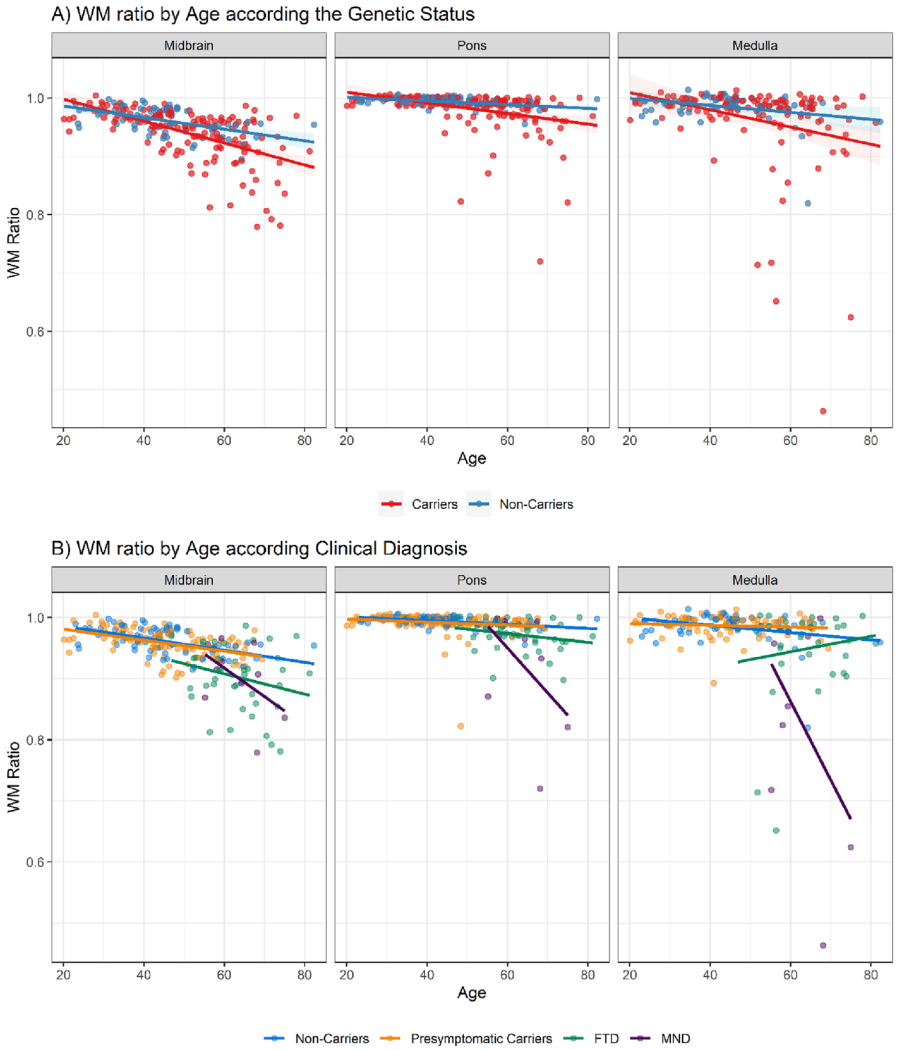

Fig. 4 Scatter plot showing the correlation between the WM ratio and age for each of the studied groups: the whole brainstem, the midbrain, the pons, and the medulla oblongata

non-linear regressions, but they did not improve the linear model significatively.

Brainstem WM ratio and age trajectories according to the clinical status

Finally, we assessed the brainstem WM trajectories by age according to the clinical status to evaluate if subjects with different clinical diagnoses present different trajectories of brainstem WM during the disease. In that sense, the MND group showed a greater loss of WM by age in all regions compared to FTD patients, the medulla being the region with the highest effect of age in WM loss for this group of patients (Fig. 4B; Table 3).

Discussion

In the present study, we used brain MRI scans from the GENFI consortium to investigate whether corticospinal and corticobulbar tracts neurodegeneration is measurable in the brainstem structures of *C9orf72* carriers. Symptomatic *C9orf72* expansion carriers showed consistent alterations in brainstem WM that correlated with clinical severity. Subjects with motor neuron symptoms presented more WM loss in the brainstem than those without motor symptoms.

Brainstem neuroimaging abnormalities have been investigated by means of semi-automated volumetry methods, especially in progressive supranuclear palsy [21, 34]. Concerning *C9orf72* expansion carriers, previous work found no structural volumetric gray matter (GM) impairment in the brainstem [16, 35]. However, the evaluation of brainstem WM in *C9of72* was lacking. Here, we developed a measure of WM degeneration consisting of the proportion of the brainstem volume occupied by WM. We chose the proportion of WM instead of its whole volume to avoid differences due to different brain sizes. Assessed in the non-carriers as controls, this WM ratio showed values close to 1, reflecting that, in normal conditions, the relative GM volume in the brainstem is scarce. However, these high values might reflect an overestimation of the WM volumes. Previous neuroimaging studies have shown that small brainstem pathways might be artificially enlarged due to the inclusion of crossing fibers [36, 37]. Despite this limitation, our work found differences between groups, reflecting the utility of this measure as a neuroimaging biomarker.

We found a lower brainstem WM ratio in symptomatic *C9orf72* carriers compared to non-carriers regardless of their clinical phenotype. These differences were found in the three sub-structures (midbrain, pons, and medulla oblongata), suggesting widespread neurodegeneration of the corticospinal tracts. No differences were found between presymptomatic carriers and controls. This finding would suggest that the neurodegeneration of the WM tracts appears near the onset of the symptoms, pointing to the brainstem WM ratio as a biomarker of conversion in *C9orf72* carriers. Whether the WM neurodegeneration occurs before or after the symptom's onset remains unclear. Our study did not show WM changes in the presymptomatic carriers' group. By contrast, Querin et al. recently observed spinal cord WM atrophy in presymptomatic *C9orf72* carriers who were older than 40 years [23]. This could suggest that the spinal cord would show signs of WM alterations before the brainstem, or it could be the result of including participants who were far from the estimated year of onset in our study. The observed relationship between the brainstem WM ratio and age sheds light on this point. Overall, all subjects showed a mild loss of WM over the years with both groups, carriers, and non-carriers, showing no differences until the 6th decade of life

Significant group differences ($p<0.05$) are highlighted in bold

when *C9orf72* carriers suffer a greater WM loss, especially in the midbrain. Of note, this decade of life coincides with the onset of symptoms reported recently by Moore et al., reinforcing the idea of the brainstem WM ratio as a possible biomarker of conversion [9].

In consonance with neuropathological studies, patients with MND showed significantly more atrophy in the pons and especially in the medulla oblongata compared to FTD. Similar results were found in the multivariate analyses, where patients presenting in form of MND suffered further loss of WM ratio than the other groups, particularly in the medulla oblongata (Fig. 4B). We hypothesize that this greater loss of WM in *C9orf72* carriers is due to the neurodegeneration of the corticospinal and corticobulbar tracts in patients who develop motor neuron symptoms. These results suggest that the brainstem WM ratio, especially in the medulla oblongata, could be an interesting biomarker to predict motor neuron symptoms in *C9orf72* carriers. This finding is particularly relevant because the form of onset in *C9orf72* carriers is highly unpredictable, and patients with motor neuron symptoms have a worse overall prognosis. Moreover, most neuroimage biomarkers studied in *C9orf72* carriers have focused on cortical atrophy, but MND patients may present only subtle cortical atrophy, especially in those with bulbar onset where, theoretically, brainstem changes were supposed to be more remarkable.

Additionally, we evaluated if the WM ratio could monitor the disease progression. For this purpose, we assessed the WM ratio across the different disease stages measured with the CDR®+NACC-FTLD scale. Here, a biological gradient was found, with patients in more advanced stages showing lower WM ratios. This loss of WM was greater in the midbrain with significant differences between the CDR = 0.5 and the CDR = 1 stages in the region. We also found a negative correlation between the CDR®+NACC-FTLD sum of boxes and the WM ratio in the brainstem. This correlation was, again, strongest in the midbrain ($r = -0.60$). We also evaluated the correlation between the WM ratio and the severity of the motor neuron symptoms in *C9orf72* carriers. A negative correlation between the WM ratio and the ALSFRS-R was found in all the brainstem regions. However, this correlation was highly influenced by subjects without motor neuron symptoms.

Our study has some limitations. First, it is important to consider that the brainstem WM visualization is challenging due to the small size of the pathways, the high density of their distributions, lower contrast, and image distortions associated with in vivo acquisitions. As mentioned before, brain volumetry could overestimate WM volumes. Despite this possible limitation, we found that our methodology is valid to find differences between groups. To support and complement our results, other MRI modalities such as Diffusion tensor imaging (DTI) may be studied in the future. Another limitation is the relatively small sample size. Even using data from a multicentric study, in some analyses, especially for the MND subgroup, the number of subjects was low, due to the low prevalence of the disease. This small number of MND patients did not allow us to study differences between subjects with bulbar or spinal onset.

In conclusion, our data suggest that WM loss in the brainstem might be a marker of clinical conversion and disease progression monitoring in C9orf72 carriers, especially in carriers presenting with motor neuron symptoms. Additional studies with extended follow-up data might be needed to confirm these findings.

Acknowledgements The authors thank all the volunteers for their participation in this study. SBE is a recipient of the Joan Rodés Josep Baselga grant from the FBBVA. This study was partially funded by Fundació Marató de TV3, and Instituto de Salud Carlos III, Spain (grant no. 20143810 and PI20/0448 to RSV). The GENFI study has been supported by the Medical Research Council UK, the Italian Ministry of Health and the Canadian Institutes of Health Research as part of a Centres of Excellence in Neurodegeneration grant, as well as other individual funding to investigators. KM has received funding from an Alzheimer's Society PhD studentship. JDR acknowledges support from the National Institute for Health Research (NIHR) Queen Square Dementia Biomedical Research Unit and the University College London Hospitals Biomedical Research Centre, the Leonard Wolfson Experimental Neurology Centre, the UK Dementia Research Institute, Alzheimer's Research UK, the Brain Research Trust and the Wolfson Foundation. JCvS was supported by the Dioraphte Foundation grant 09-02-03-00, the Association for Frontotemporal Dementias Research Grant 2009, The Netherlands Organization for Scientific Research (NWO) grant HCMI 056-13-018, ZonMw Memorabel (Deltaplan Dementie, project number 733 051 042), Alzheimer Nederland and the Bluefield project. CG have received funding from JPND-Prefrontals VR Dnr 529-2014-7504, VR: 2015-02926, and 2018-02754, the Swedish FTD Initiative-Schörling Foundation, Alzheimer Foundation, Brain Foundation and Stockholm County Council ALF. DG has received support from the EU Joint Programme – Neurodegenerative Disease Research (JPND) and the Italian Ministry of Health (PreFrontALS) grant 733051042. JBR is funded by the Wellcome Trust (103838) and the National Institute for Health Research (NIHR) Cambridge Biomedical Research Centre. MM has received funding from a Canadian Institutes of Health Research operating grant and the Weston Brain Institute and Ontario Brain Institute. RV has received funding from the Mady Browaeys Fund for Research into Frontotemporal Dementia. EF has received funding from a CIHR grant #327387. JDR is an MRC Clinician Scientist (MR/M008525/1) and has received funding from the NIHR Rare Diseases Translational Research Collaboration (BRC149/NS/MH), the Bluefield Project and the Association for Frontotemporal Degeneration. MS was supported by a grant 779257 "Solve-RD" from the Horizon 2020 research and innovation programme.

Funding The funding sources have no role in the design of this study, its execution, analyses, interpretation of the data, or the decision to submit results.

Data availability statement The dataset analyzed for the current study is from the research consortia GENFI. Data will be shared according to the GENFI data sharing agreement, after review by the GENFI data access committee with final approval granted by the GENFI steering committee.

Declarations

Conflicts of interest JBR reports consultancy for Asceneuron, Biogen, UCB, and SV Healthcare and research grants from Janssen, Lilly, and AZ-Medimmune. JL reports speakers fees from Bayer Vital, consulting fees from Axon Neuroscience, nonfinancial support from Abbvie, compensation for part time CMO from MODAG, author fees from Thieme medical publishers and from W. Kohlhammer GbmH medical publishers, all outside the submitted work. JDR Rohrer has served as a consultant for Biogen, Ionis, Alector, Wave Life Sciences, and Astex. RSV has served in Advisory boards Meetings for Wave Life Sciences, Ionis and Novo Nordisk and received personal fees for participating in educational activities from Janssen, Roche Diagnostics and Neuroxpharma and funding to her institution for research projects from Biogen and Sage Pharmaceuticals. The other authors report no disclosures relevant to the manuscript.

4. 1 INFORME DE LES DIRECTORES

Aquesta tesis doctoral per compendi d'articles ha estat realitzada sota la nostra direcció i considerem que reuneix les condicions necessàries. Inclou sis articles, dels quals 4 ja han estat publicats o acceptats i els altres estan sota revisió.

Títol	**Nom de la revista; DOI**	**Any**	**IF (2022); Quartil**	**Contribució personal**
Evaluating the performance of Bayesian and frequentist approaches for longitudinal modeling: application to Alzheimer's disease	Scientific Reports; 10.1038/s41598-022-18129-4	2022	4,6; Q2	Disseny de l'estudi, recol·lecció de les dades, anàlisi dels resultats, interpretació dels resultats, redacció i revisió del manuscrit
Cortical thickness modeling and variability in Alzheimer's disease and frontotemporal dementia.	Acceptat en Journal of Neurology	---	6,0; Q1	Disseny de l'estudi, recol·lecció de les dades, processament de les imatges de RM, anàlisi dels resultats, interpretació dels resultats, redacció i revisió del manuscrit
Classifying Alzheimer's disease and frontotemporal dementia using machine learning with cross-sectional and longitudinal magnetic resonance imaging data	Human Brain Mapping; 10.1002/hbm.26205	2023	4,8; Q1	Disseny de l'estudi, recol·lecció de les dades, processament de les imatges de RM, anàlisi dels resultats, interpretació dels resultats, redacció i revisió del manuscrit

Beyond group classification: probabilistic differential diagnosis of frontotemporal dementia and Alzheimer's disease with MRI and CSF biomarkers	En revisió	---	---	Disseny de l'estudi, recol·lecció de les dades, processament de les imatges de RM, anàlisi dels resultats, interpretació dels resultats, redacció del manuscrit
The Cortical Asymmetry Index (CAI) for subtyping dementia patients	En revisió	---	---	Disseny de l'estudi, recol·lecció de les dades, processament de les imatges de RM, anàlisi dels resultats, interpretació dels resultats, redacció del manuscrit
Loss of brainstem white matter predicts onset and motor neuron symptoms in *C9orf72* expansion carriers: a GENFI study	Journal of Neurology; D10.1007/s 00415-022-11435-x	2023	6,0; Q1	Disseny de l'estudi, recol·lecció de les dades, processament de les imatges de RM, anàlisi dels resultats, interpretació dels resultats, redacció i revisió del manuscrit

El sisè treball ha estat realitzat en contribució equivalent pels dos primers autors (Agnès Pérez Millan i el Dr. Sergi Borrego Écija). Cap dels treballs que formen la present tesi han estat utilitzats implícitament o explícitament en cap altra tesi.

Signat,

Dra. Roser Sala Llonch Dra. Raquel Sánchez-Valle

4.2 RESUM GLOBAL DELS RESULTATS

Primer treball:

En aquest treball explorem el volum de l'hipocamp amb pacients de la base de dades longitudinals ADNI (adni.loni.usc.edu). Avaluem quina aproximació estadística, la freqüentista o la bayesiana, és l'òptima per estudiar models longitudinals tant en bases de dades homogènies (tots els pacients tenen el mateix nombre de vistes) com heterogènies (manquen visites d'alguns pacients). Per això, creem models d'efectes lineals mixts (ELM) en els dos marcs estadístics. En una base heterogènia en què no tots els pacients tenen el mateix nombre de visites, però amb un nombre molt elevat de pacients (1250 participants), trobem que els dos enfocaments són capaços d'identificar els mateixos grups de pacients. Així, el comportament que presenten les dues aproximacions és molt similar. Tot i això, l'enfocament bayesià necessita molt més poder computacional per poder estudiar les trajectòries d'aquests pacients.

Tanmateix, si la base de dades no és tan extensa, les dues aproximacions estadístiques ja no es comporten de la mateixa manera. Per estudiar aquest fet partim d'una base de dades homogènia extensa (N=670 participants, 4 visites cada un). Posteriorment, realitzem dues simulacions mitjançant l'eliminació progressiva de dades. En la primera, per estudiar el mínim nombre de subjectes que permeti separar els grups, trobem que l'enfocament bayesià va ser lleugerament més estricte. En la segona, per avaluar l'efecte de la manca de punts, l'aproximació bayesiana presenta un poder estadístic superior a la freqüentista, ja que a mesura que es redueixen el nombre de visites de forma aleatòria, arriba

un punt que l'aproximació freqüentista no pot estimar el model. En canvi, l'aproximació bayesiana, no té aquesta limitació. Així, l'enfocament bayesià és més robust per a bases de dades desequilibrades i disperses amb un nombre diferent de mesures entre subjectes. En canvi, l'aproximació freqüentista és computacionalment més senzilla, però falla en la modelització de dades amb un gran nombre de valors que falten.

Segon treball:

En aquest treball hem implementat models d'estimació del gruix cortical segons l'edat cronològica per persones sanes, i segons els anys de durada de la malaltia per pacients amb MA i DFT. Els models han estat creats amb una regressió de suport vectorial (RSV) i amb dades de RM estructural de la Unitat d'Alzheimer i altres trastorns cognitius de l'Hospital Clínic de Barcelona (379 pacients amb una visita i 144 pacients amb 2-3 visites). Amb aquests models podem identificar les variacions individuals com a desviacions de la norma, utilitzant models específics per persones sanes, MA i DFT. Amb el model generat amb persones sanes, veiem que el model s'adapta al seu propi grup, però que els pacients amb MA i DFT presenten una variabilitat molt elevada. A més, les desviacions segons aquest model per pacients amb MA correlacionen amb les puntuacions dels anys de durada de la malaltia i MMSE, mentre que els pacients amb DFT no presenten correlacions.

Posteriorment, usem els models específics per la MA i la DFT per estudiar les desviacions del model dins de cada grup en relació amb biomarcadors bioquímics i les puntuacions del MMSE. Per als pacients amb DFT, trobem una correlació inversa significativa entre els nivells de LCR-NfL i la desviació del model a la majoria de les regions del cervell, proporcionant evidències addicionals de la relació entre la imatge i els biomarcadors bioquímics en DFT. A més, trobem una correlació positiva per als pacients amb MA entre les puntuacions MMSE i la desviació del model en diverses regions.

Finalment, utilitzem les dades longitudinals per avaluar la capacitat dels models per obtenir prediccions individuals dels valors futurs del gruix cortical. Trobem que els models de persones sanes i MA, són capaços de predir les futures vistes, en canvi, el model de DFT mostra una elevada variabilitat.

Tercer treball:

En aquest treball hem implementat un algoritme de classificació automàtica per diferenciar pacients amb MA i DFT i persones sanes amb RM estructural. La combinació d'un primer algoritme on es redueixen el nombre de les variables segons una aproximació no supervisada i posteriorment un algoritme de classificació automàtic supervisat ens permet classificar els grups amb dades transversals i longitudinals. L'algoritme ha estat entrenat i testejat amb dades de la Unitat d'Alzheimer i altres trastorns cognitius de l'Hospital Clínic de Barcelona (339 pacients amb una visita i 114 pacients amb 2 visites).

L'algorisme implementat classifica a nivell transversal els pacients sans versus MA i versus DFT amb un 83,3% i un 82,1% de precisió respectivament. Aquesta precisió augmenta fins a un 90,0% i un 88,0% respectivament amb dades longitudinals. Quan estudiem la classificació entre MA versus DFT aconseguim una precisió del 63,3% a nivell transversal i del 75,0% a nivell longitudinal. Finalment, la classificació MA versus DFT versus persones sanes assoleix una precisió del 60,7% i del 71,3% per a les dades transversals i longitudinals, respectivament. Per tant, observem que l'enfocament longitudinal proporciona un rendiment superior al transversal, assolim millors precisions en el diagnòstic automàtic per tots els casos.

Quart treball:

Aquest treball consisteix a implementar un algoritme de classificació automàtica que retorna el diagnòstic i les probabilitats individuals associades a cada grup. El treball s'ha fet amb dades transversals de RM estructural i biomarcadors de LCR de la base de dades de la Unitat d'Alzheimer i altres trastorns cognitius de l'Hospital Clínic de Barcelona que inclou 491 pacients (persones amb MA, persones amb DFT i persones sanes). L'algoritme és capaç de discriminar amb èxit els pacients amb DFT i MA amb bona precisió, i permet identificar els subtipus de variants clíniques de la DFT. Només amb dades de RM, obtenim precisions del 88% en la classificació MA versus persones sanes, 87% per DFT versus persones sanes, 82% per MA versus DFT i 80% en diferenciar els tres grups clínics. Un total del 74% dels participants amb DFT i el 73% dels participants amb

MA tenen una probabilitat alta (≥80%) de tenir un diagnòstic precís en la comparació de DFT versus MA.

Les dades dels nivells de NfL i 14-3-3 en LCR s'estudien primer de forma independent i en combinació amb dades de RM. Els resultats que s'extreuen d'aquesta informació depenen de cada una de les comparacions. Quan es comparen els pacients amb MA respecte persones sanes, els nivells de LCR són suficients per assolir un diagnòstic precís. En el cas dels pacients amb DFT versus les persones sanes, tant les dades solament de RM o LCR, com la combinació d'ambdues modalitats donen resultats similars. Finalment, per diferenciar pacients amb MA versus DFT, la combinació de les dades de RM i LCR, és la que aconsegueix el diagnòstic més precís i el nombre més nombrós de pacients amb una probabilitat major del 80% de tenir un encert en el diagnòstic.

Cinquè treball:

En aquest treball mesurem les asimetries del còrtex cerebral amb un índex que nomenem Índex d'Asimetria Cortical (CAI). L'estudi es realitza amb dades de la Unitat d'Alzheimer i altres trastorns cognitius de l'Hospital Clínic de Barcelona que inclou 554 pacients (persones amb DFT, persones amb MA i persones sanes). El CAI és una mesura derivada de la teoria de la informació que ens permet obtenir com és d'asimètric el cervell de manera individual. El CAI ens permet diferenciar les persones sanes dels participants amb demència, seguidament la DFT de la MA, i finalment els diferents fenotips de la DFT. A més a més, longitudinalment permet identificar els canvis en l'asimetria cerebral al llarg del

temps pels pacients amb DFT. Finalment, duem a terme unes anàlisis de clústers amb els valors del CAI pels pacients amb DFT i per MA. Identifiquem dos clústers per cada demència, que presenten diferències significatives amb nivells de biomarcadors de líquid cefalorraquidi i de sang. Els pacients amb DFT s'agrupen en dos clústers, un estaria format principalment pels pacients amb la variant semàntica i l'altre per la variant no fluent i la conductual. Els dos clústers presenten diferències en els nivells de NfL tant en LCR com en sang. Els pacients amb MA mostren dos clústers també, que a priori no hem sigut capaços d'interpretar des de la clínica, però que es diferencien amb els nivells de GFAP en sang.

Sisè treball:

En aquest treball utilitzem la RM estructural per mesurar la substància blanca de les estructures del tronc encefàlic dels portadors de la mutació C9orf72. Les dades d'aquest estudi de DFT genètica són del consorci internacional i multicèntric GENFI (https://www.genfi.org/), i formen part de l'estudi 102 portadors asimptomàtics de la mutació C9orf72, 72 portadors simptomàtics de la mutació C9orf72 i 75 no portadors. Estudiem les diferències que puguin presentar les diferents estructures del tronc encefàlic per aquests pacients i trobem que amb aquestes estructures podem diferenciar els diferents pacients, però no les persones sanes de les asimptomàtiques, però sí que es diferencien els pacients amb DFT i els pacients amb DFT que presenten símptomes de neurones motores. També realitzem regressions lineals per avaluar les interaccions entre

els diferents grups clínics i l'edat. En aquest cas trobem que els pacients amb símptomes de neurones motores presenten més pèrdua de substància blanca al tronc cerebral que els que no tenien símptomes motors. Finalment, els portadors de l'expansió C9orf72 simptomàtics mostren alteracions consistents en la substància blanca del tronc cerebral que es correlaciona amb la gravetat clínica.

CAPÍTOL 5

Discussió

Els treballs que conformen la present tesi doctoral pretenen aportar informació de les possibilitats i limitacions dels models matemàtics amb dades de RM estructural per l'estudi de la MA i la DFT. També volen ampliar el coneixement sobre els marcadors útils pel diagnòstic diferencial d'aquestes demències i les seves variants clíniques, i estudiar la complementarietat entre els biomarcadors d'imatge i els biomarcadors bioquímics. Així mateix, la present tesi doctoral pretén aprofundir en l'heterogeneïtat clínica que presenten aquestes demències estudiant la variabilitat individual dels pacients amb MA i DFT respecte de la tendència grupal en funció del temps.

En el primer treball (104) vam avaluar si l'homogeneïtat o heterogeneïtat de les dades longitudinals en bases de dades extenses en neuroimatge té alguna implicació a l'hora de realitzar l'estudi estadístic de les trajectòries. Per aquest estudi ens vam centrar en la MA, tot i que els resultats es poden extrapolar a altres demències o malalties. Això ho vam fer, ja que teníem accés a una base de dades molt extensa com és ADNI amb 1250 pacients amb 5 visites. I alhora, podíem utilitzar el volum de l'hipocamp, que és un biomarcador de MA d'imatge en RM estructural que ha estat ben descrit i és acceptat en els actuals criteris de diagnòstic de la MA (16,17,105–107), així que ens permetia centrar-nos en l'aproximació estadística. Per això, vam crear models ELM segons l'aproximació freqüentista i la bayesiana per estudiar les diferències entre els grups al llarg del temps i explorar quina aproximació és la més recomanable en situacions diverses. En primer lloc, vam trobar que els dos enfocaments coincidien en els resultats de les proves d'hipòtesis nul·les amb tot el conjunt de dades amb els prèviament descrits en la literatura amb dades ADNI (60,67,108). En aquest cas, la diferència que presentarien les dues aproximacions seria el cost computacional, ja que l'enfocament bayesià va necessitar molt més poder computacional i temps per poder estudiar les trajectòries respecte a l'aproximació freqüentista. Ara bé, s'ha de valorar la diferent interpretació que presenten cada una de les aproximacions, no solament el cost de l'estimació del model. L'aproximació bayesiana proporciona un marc més interpretable, ja que es basa en l'estimació directa a partir de la distribució de la població representada per la distribució posterior, en lloc d'estimar a partir de la distribució mostral hipotètica com passa en l'enfocament freqüentista. Així que, en entorns clínics l'aproximació bayesiana pot oferir una interpretació més directa, perquè els resultats es poden interpretar

de manera probabilística, contràriament a l'aproximació freqüentista que no accepta aquesta interpretació encara que molts investigadors la utilitzen (71,73). Tanmateix, si la base de dades no és tan extensa i presenta molts pacients als quals els hi manquen visites, les dues aproximacions estadístiques ja no es comporten de la mateixa manera. En aquest sentit, un inconvenient important per al modelatge ELM segons un enfocament freqüentista és la necessitat de tenir més mostres de participants que efectes aleatoris per estimar el model. En canvi, l'enfocament bayesià permet estimar el model fins i tot amb un nombre elevat de punts que falten a la base de dades. Més concretament, els nostres resultats van mostrar que el model ELM segons un enfocament bayesià és possible en una base de dades de 4 punts de temps que té aproximadament 2 valors que falten per a cada participant, cosa que suggereix que per a la modelització longitudinal en bases de dades escasses s'hauria de triar el marc bayesià. Altres estudis han demostrat que l'estadística bayesiana supera algunes de les limitacions de la inferència estadística clàssica en bases de dades no homogènies (68,109). En conjunt, destaquem la necessitat de conèixer les característiques de la mostra de dades per poder inferir la correcta interpretació dels resultats. Així que, en l'estudi vam proposar que l'enfocament bayesià és més robust per a bases de dades desequilibrades i disperses amb un nombre diferent de mesures entre subjectes.

En el segon treball (acceptat) ens vam centrar a implementar models específics grupals per MA, DFT i persones sanes del gruix cortical segons l'edat cronològica per a persones sanes i segons els anys de malaltia per a pacients amb MA i DFT, per estudiar les desviacions que presenten respecte a les persones sanes i la tendència grupal. Donat que en el primer treball, havíem observat, igual que

altres autors (110–112) que un model basat en probabilitats presenta més avantatges, en aquest segon treball vam seguir en aquesta línia i el model del gruix cortical és estimat amb una RSV, que deriva dels models d'aprenentatge automàtic d'intel·ligència artificial que té una base probabilística.

Amb aquests models vam realitzar un estudi de la variabilitat que presenta cada individu respecte de la tendència grupal i vam associar aquestes desviacions amb els símptomes en el cas dels pacients. Pels pacients amb MA, vam trobar que les desviacions individuals del model correlacionaven amb les puntuacions del MMSE, sobretot en els lòbuls temporal i parietal, on les desviacions individuals més elevades del model s'associaven als individus amb puntuacions més elevades de MMSE. La relació entre el MMSE i el gruix cortical ha estat ben descrita prèviament (113–115). En el nostre treball, vam poder identificar que els pacients amb puntuacions més elevades de MMSE són aquells en els que el gruix cortical es desvia més de l'esperat segons els anys de malaltia. En el cas dels pacients amb DFT, vam trobar una correlació inversa entre els nivells de NfL en LCR i la desviació del model, proporcionant evidències addicionals a les ja descrites per altres autors sobre la relació entre la imatge i els biomarcadors de fluids per aquests pacients. Per exemple, els nivells de NfL s'han suggerit com a factor de gravetat per la DFT (38,39). Els nivells alts de NfL van estar associats a les desviacions del model del gruix cortical més baixes. Per tant, els pacients amb patrons de gruix cortical que s'adapten bé al model tenen nivells més elevats de NfL en LCR, així que el model de gruix cortical pels pacients amb DFT va capturar la tendència de neurodegeneració. En canvi, els nivells més baixos de NfL corresponien a pacients que s'allunyaven més del model DFT, similar al que s'ha

descrit com una DFT no progressiva (116). En estudiar les diferents variants clíniques de la DFT, trobem que la vcDFT és la que tindria més contribució en el model, ja que les altres variants APP mostren una desviació més alta. Aquests resultats estan en la línia del que s'ha descrit prèviament, on la DFT és una demència heterogènia (30,36,98). A més, en altres estudis d'aquesta tesi, utilitzant algoritmes de classificació automàtica, també observem que la variant vcDFT té una contribució més important a l'hora de definir les tendències o patrons dels pacients amb DFT i on els patrons d'importància no coincideixen entre les diferents variants clíniques de la DFT. Tenint en compte les dues troballes, necessitaríem crear models específics per cada una de les variants per poder predir els canvis en el gruix cortical en detall per aquests pacients.

Els resultats del segon treball, tot i que estava centrat en l'estudi de la variabilitat, també ens van permetre predir el gruix cortical en visites futures segons l'edat per persones sanes i segons els anys de malaltia per pacients amb MA. En canvi, pels pacients amb DFT, no vam poder assolir unes prediccions fiables de les seves futures vistes a causa de l'alta variabilitat que presentaven els resultats.

Els resultats del segon estudi van mostrar que els pacients amb DFT i MA mostren una variabilitat individual tant a nivell transversal com longitudinal en les imatges de RM estructural que podrien ser útils per un diagnòstic personalitzat. Per això, en el tercer treball (117) que forma aquesta tesi ens vam centrar a estudiar la utilitat de l'aprenentatge automàtic per al diagnòstic diferencial de la DFT i la MA a nivell transversal i longitudinal amb dades de RM estructural, i alhora obtenir interpretabilitat dels resultats. Per realitzar aquesta classificació entre pacients vam utilitzar el classificador MVS, que és el model

d'aprenentatge automàtic supervisat àmpliament utilitzat amb dades de neuroimatge per pacients amb MA i DFT (53,94,96,118–121). Però, aquest model no permet les classificacions amb dades longitudinals, és per això, que vam aplicar tècniques no supervisades abans de realitzar la classificació amb el MVS. Aquestes tècniques van ser una anàlisi de components principals (ACP) per l'estudi transversal i el seu anàleg l'anàlisi de múltiples factors (AMF) per les dades longitudinals (122). Això, ens va permetre fer la classificació tant a nivell transversal com longitudinal i poder obtenir uns resultats interpretables, ja que solament ens vam quedar amb la primera component, així que amb les contribucions d'aquesta component vam poder estudiar quines són les variables més importants per la classificació. Aquesta combinació d'algoritmes supervisats i no supervisats ens va permetre assolir uns nivells de precisió tant a nivell transversal com longitudinal alts. L'algoritme va classificar a nivell transversal els pacients sans versus MA i versus DFT amb un 83% i un 82% de precisió respectivament. Aquesta precisió va augmentar fins a un 90% i un 88% amb dades longitudinals, per MA i DFT respectivament. Quan vam estudiar la classificació entre MA versus DFT vam aconseguir una precisió del 63% a nivell transversal i del 75% a nivell longitudinal. Finalment, la classificació MA versus DFT versus persones sanes va assolir una precisió del 61% i del 71% per a les dades transversals i longitudinals, respectivament. Aquestes precisions estan dins del rang dels estudis prèviament publicats, o són superiors (94–96,123–125). Les diferències entre aquest estudi i els prèviament publicats per altres grups són que vam poder classificar dades longitudinals amb un MVS i millorar els resultats transversals, i que vam obtenir els patrons de les regions cerebrals més importants per la classificació. En aquest estudi, ens vam centrar a assolir un

algoritme d'aprenentatge automàtic amb una alta precisió que permetés diferenciar els pacients amb MA, DFT i les persones sanes, però donant molta importància a la seva interpretabilitat, no ens vam focalitzar solament en maximitzar el rendiment. L'algoritme ens va permetre aconseguir un patró d'atròfia diferent per cada una de les malalties, amb els pesos de les tècniques no supervisades, identificant les regions més rellevants per realitzar el diagnòstic automàtic. En general, vam trobar que les regions més importants per la classificació coincidien amb els patrons patològics d'acord amb la literatura de la MA i la DFT (96,126). Tanmateix, aquests algoritmes cerquen interaccions robustes entre les diferents variables que s'introdueixen (en el nostre cas les regions cerebrals), per la qual cosa és possible que apareguin regions que no coincideixen amb els patrons diferencials de MA o DFT o patrons superposats. Treballs anteriors (55,127,128) també han trobat alguns patrons de degeneració superposats entre les dues demències.

La principal limitació del tercer treball és que no vam poder estudiar la fiabilitat amb què l'algoritme dona el resultat del diagnòstic. Vam observar que, més enllà del diagnòstic diferencial entre la MA i la DFT necessitem resultats per establir si els diagnòstics són fiables o aleatoris. Per això, en el quart estudi (no publicat) d'aquesta tesi, vam decidir implementar un altre algoritme, aquest cop a nivell transversal que ens permetés obtenir aquest diagnòstic diferencial de la MA i la DFT conjuntament amb la fiabilitat dels resultats, i que fos interpretable, com ja ho era el creat anteriorment. Així, vam desenvolupar mètodes de classificació calibrada i vam considerar que els participants amb una probabilitat major al 80% per algun dels diagnòstics tindrien una classificació fiable. Els pacients amb una probabilitat individual menor al 80%, estaven dins del que anomenem zona

de baixa confiança del diagnòstic. Vam identificar aquests pacients com els que necessitarien més proves clíniques per poder realitzar el seu diagnòstic diferencial. I, per això, vam anar un pas més enllà i vam decidir avaluar si la RM i els nivells de LCR (NfL i 14-3-3, biomarcadors de neurodegeneració) millorarien la classificació. En aquest estudi, com en l'anterior, vam assolir precisions de l'orde, o millors, que les prèviament descrites en la literatura per discriminar la MA i la DFT amb dades de RM estructural. En el nostre cas, tenim 88% per MA versus persones sanes, 87% per DFT versus persones sanes, 82% per MA versus DFT i 80% per discriminar els tres grups clínics (53,62,93,96,127,129–133). A més, en aquest segon estudi de classificació automàtica per pacients amb MA i DFT, vam ser capaços de millorar els nostres propis resultats, mantenint la interpretabilitat i, d'altra banda, obtenint un valor de la fiabilitat diagnòstica dels resultats que en l'estudi previ no teníem. Ara bé, en l'estudi previ, podíem classificar amb dades longitudinals i vam observar que aquestes aportaven una informació que ens permetia millorar el nostre diagnòstic. Queda per explorar, doncs, la combinació dels estudis longitudinals amb els algoritmes de classificació calibrada per assolir nivells de confiança diagnòstica en dades longitudinals.

Entre els resultats clau d'aquest quart estudi, vam trobar que el 74% dels participants amb DFT i el 73% amb MA mostraven una probabilitat individual major al 80% d'estar ben classificats per l'algoritme en la comparació DFT versus MA. També, vam explorar la classificació automàtica per les variants clíniques de la DFT (vcDFT, vsAPP i vnfAPP) amb unes precisions superiors a les descrites prèviament (53,77,96). En primer lloc, pel que fa a les comparacions amb

persones sanes, per a vcDFT, vam obtenir una precisió del 91%, i en el cas dels participants APP, una precisió del 93%. Quan vam classificar vcDFT i APP per separat contra MA, vam aconseguir precisions de fins al 90% per als dos casos. Tanmateix, quan vam intentar classificar vcDFT versus APP, assolim una precisió del 68% que no seria acceptable des del punt de vista clínic.

En aquest quart treball, com vam realitzar en el tercer treball d'aquesta tesi, obtenim uns patrons que ens indiquen la importància de cada regió en la classificació, tot i que en aquest cas han estat mesurats amb un test de permutacions, ja que és un algoritme diferent del descrit prèviament. El volum de la substància grisa de l'hipocamp, el putamen i l'amígdala van ser essencials per diferenciar MA de persones sanes. Per altra banda, les regions corticals van ser les més importants per diferenciar la DFT de persones sanes, especialment les regions occipitals, parietals i frontals. Aquests resultats estan d'acord amb les troballes amb mètodes d'anàlisi més clàssics (19,40,134–137) i amb els estudis previs que s'han realitzat en aquesta tesi. Finalment, pel que fa a les variants clíniques de la DFT, les regions frontals van ser les més destacades per la vcDFT i les temporals i l'hipocamp per la variant APP, també ha estat descrit prèviament (134,136,137).

Finalment, en aquest quart treball vam observar que la combinació de la RM i els nivells de LCR, solament seria necessària per al diagnòstic diferencial de la MA i la DFT. En canvi, quan vam estudiar el diagnòstic versus una persona sana, per la MA, la RM no era necessària i per la DFT, amb una de les dues proves era suficient per obtenir la mateixa fiabilitat en el diagnòstic. Aquesta proposta d'algoritme ens permet no solament ajudar en el diagnòstic diferencial dels

pacients, sinó també en avaluar quines proves serien necessàries per a cada pacient individualment.

En els treballs 3 i 4, vam crear uns algoritmes d'aprenentatge automàtic interpretables. En aquests, en estudiar les regions més importants, vam observar que no són patrons simètrics. Per tant, en el cinquè treball (no publicat), vam estudiar l'asimetria cerebral per avaluar si podia ajudar en el diagnòstic diferencial de la DFT i la MA o, fins i tot, en la diferenciació de les diferents variants de la DFT (30,98,138–141). Hi ha treballs anteriors que estudien les asimetries cerebrals en DFT i MA, però majoritàriament avaluen l'asimetria de manera visual. Tot i que s'han fet alguns estudis per quantificar les asimetries de manera sistemàtica (138,142–144), són reduïts. Nosaltres vam escollir una metodologia més complexa basada en la teoria de la informació per obtenir l'estimació d'un índex asimètric. Aquest índex d'asimetria cerebral proposat es basa en l'entropia de les imatges de RM que nomenen Índex d'Asimetria Cortical (CAI). Aquesta mesura ens va permetre diferenciar les persones sanes de les que pateixen demència (MA i DFT), les dues demències i els fenotips de la DFT, mostrant que la vsAPP és la més asimètrica. Quan vam estudiar l'asimetria al llarg del temps, vam trobar un augment d'aquesta pels pacients amb DFT, en canvi, en la MA no vam detectar cap diferència al llarg del temps en aquesta mesura.

Una anàlisi no supervisat de clústers, ens va permetre agrupar els pacients amb DFT i MA en dos subgrups segons la seva asimetria cerebral. Al ser un estudi no supervisat, vam voler donar una explicació interpretable dels resultats mitjançant dades clíniques i de biomarcadors. Entre els dos subgrups de pacients amb DFT,

el clúster més asimètric agrupava els pacients amb vsAPP i l'altre clúster amb els pacients amb vcDFT i vnfAPP. Aquests dos grups alhora es diferenciaven segons els nivells de NfL en LCR i sang. Això ens va fer suggerir que els nivells de NfL (en LCR i sang) s'associen directament amb l'asimetria cerebral. Treballs previs han demostrat l'associació dels nivells de NfL amb l'atròfia cerebral (37,38,49). No obstant això, no estudien l'associació entre els nivells de NfL i l'asimetria cerebral. A l'estudiar els dos clústers de MA, no vam ser capaços de trobar una explicació basada en el perfil clínic dels participants. Tanmateix, quan vam analitzar la seva associació amb biomarcadors de fluids vam observar que els nivells de GFAP en sang mostraven diferències significatives entre els dos clústers. Aquest biomarcador s'ha associat prèviament amb l'atròfia cerebral a causa de l'envelliment o la gravetat de la malaltia (145,146). Així i tot, la seva associació amb l'asimetria cerebral no s'ha estudiat abans. Així, en aquest cinquè estudi de la tesi vam demostrar que el CAI, definit en aquest mateix estudi, podria ser d'ajuda per a la diferenciació de les expressions clíniques o demències, per estudiar la progressió de la malaltia o per identificar subgrups.

Finalment, en el sisè treball d'aquesta tesi (147), vam aplicar mesures d'avaluació de RM en una variant concreta de DFT: la DFT genètica amb la mutació C9orf72. Les imatges de RM estructurals ens permeten mesurar la neurodegeneració del tronc encefàlic i estudiar si les anomalies que es mostren poden ser un biomarcador per la DFT amb la mutació C9orf72. Per això, primer vam utilitzar mètodes de volumetria semiautomatitzats per obtenir les diferents regions del tronc encefàlic i obtenir el volum de substància blanca. En aquest treball, vam trobar una proporció de la substància blanca del tronc encefàlic menor pels portadors simptomàtics en comparació als no portadors i les persones sanes,

aquests resultats són per les tres subestructures del tronc encefàlic (mesencèfal, pons i bulb raquidi), així que ens podria suggerir una neurodegeneració generalitzada en aquesta zona del cervell. Tanmateix, no vam identificar diferències entre les persones sanes i els portadors asimptomàtics de la mutació C9orf72, així que la neurodegeneració en aquesta zona, probablement apareix prop de l'inici dels símptomes de la malaltia. Els pacients amb DFT amb símptomes de neurones motores van mostrar una atròfia significativament major, sobretot en el bulb raquidi, que els pacients que solament presenten DFT. Aquests resultats proposen que la relació de la substància blanca del tronc encefàlic, especialment al bulb raquidi, podria ser un biomarcador interessant per predir els símptomes de la neurona motora en els portadors de la mutació C9orf72. Aquesta troballa és especialment rellevant perquè la forma d'inici en els portadors de la mutació C9orf72 és altament impredictible i els pacients amb símptomes de neurones motores tenen un pitjor pronòstic general.

CAPÍTOL 6

Conclusions

1. L'aproximació freqüentista i la bayesiana tenen comportaments similars, per l'anàlisi de dades longitudinals de ressonància magnètica en la malaltia d'Alzheimer, si les dades són homogènies, sent la freqüentista computacionalment més simple. En canvi, quan les dades són heterogènies i amb un elevat nombre de visites que manquen, només l'aproximació bayesiana permet modelar les dades.
2. Els models predictius basats en gruix cortical permeten a) mesurar i relacionar la variabilitat del gruix cortical que presenten a escala individual els pacients amb malaltia d'Alzheimer i demència frontotemporal amb marcadors clínics i biomarcadors bioquímics, b)

predir la morfologia cerebral en l'evolució de pacients amb malaltia d'Alzheimer i demència frontotemporal.

3. La combinació d'algoritmes d'aprenentatge automàtic no supervisat i supervisat permet diferenciar la malaltia d'Alzheimer i la demència frontotemporal amb una única característica derivada de la ressonància magnètica estructural, alhora que proporciona mapes d'interpretabilitat. Les dades longitudinals permeten una millora en el diagnòstic diferencial entre malalties respecte als estudis transversals.
4. L'algoritme proposat amb dades de ressonància magnètica estructural i els nivells de líquid cefalorraquidi de cadenes lleugeres de neurofilaments (NfL) i proteïna 14-3-3 proporciona un diagnòstic vàlid per la malaltia d'Alzheimer i la demència frontotemporal. A més, permet obtenir probabilitats individuals per estudiar zones de baixa confiança del diagnòstic. La contribució diferencial de la ressonància magnètica estructural i els biomarcadors en líquid cefalorraquidi depèn dels grups clínics a classificar, així, pel diagnòstic diferencial entre malaltia d'Alzheimer i demència frontotemporal, la combinació de les dues modalitats és la que assoleix la millor classificació.
5. L'índex d'asimetria cerebral suggerit, estimat amb les mesures regionals del gruix cortical i derivat de l'entropia, és capaç de diferenciar la demència frontotemporal de la malaltia d'Alzheimer, i la variant semàntica respecte a la variant no fluent i la variant conductual.
6. Els portadors simptomàtics de la mutació C9orf72 presenten una pèrdua de substància blanca del tronc encefàlic que podria ser un marcador pel

seguiment de la malaltia, indicant els pacients amb afectació de neurones motores.
