*Received February 7, 2003. Revised Manuscript Received April 10, 2003*

We used X-ray single-crystal diffraction (XRD) and high-resolution neutron powder diffraction (NPD) and performed second-harmonic generation (SHG) measurements to investigate the structural details and nonlinear optical (NLO) properties of  $\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}\text{OPO}_4$  and  $\text{RbTi}_{0.927}\text{Nb}_{0.056}\text{Er}_{0.017}\text{OPO}_4$ . We studied in detail the distribution of  $\text{Nb}^{5+}$  and  $\text{Er}^{3+}$  doping cations among the different types of  $\text{TiO}_6$  octahedra in the structure. We found that Nb cations exclusively occupied Ti(1) sites, but we did not observe a preferential occupation of the octahedra by Er. Our results established that, in  $\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}\text{OPO}_4$ , the substitution of  $\text{Ti}^{4+}$  by  $\text{Nb}^{5+}$  centers was compensated by the creation of  $\text{Rb}^+$  vacancies. The SHG measurements in these crystals reveal that these crystals are excellent nonlinear optical materials and that the absorption of the generated green light by  $\text{Er}^{3+}$  in the  $\text{RbTi}_{0.927}\text{Nb}_{0.056}\text{Er}_{0.017}\text{OPO}_4$  crystal is negligible.

## Introduction

Potassium titanyl phosphate,  $\text{KTiOPO}_4$  (KTP), is the best-known member of the family of compounds with formula  $\text{MM}'\text{OXO}_4$  ( $M = \text{K, Rb, Tl, Na, NH}_4$  or  $\text{Cs}$ ;  $M' = \text{Ti, Ge, Sn}$ ; and  $X = \text{P}$  or  $\text{As}$ ; or partial substitution in  $M$  and  $M'$  by two or more different cations).<sup>1,2</sup> Many of the crystals in this family are interesting because of their nonlinear optical (NLO) properties. KTP is particularly interesting for its application in the second-harmonic generation of 1.064- $\mu\text{m}$  Nd lasers.<sup>3</sup> All members of this family are orthorhombic, biaxial crystals and belong to the noncentrosymmetric space group  $Pna2_1$  (point group  $mm2$ ). The structure is characterized by helicoidal chains of  $M'\text{O}_6$  octahedra that are linked between them at two corners and separated by  $\text{XO}_4$  tetrahedra.<sup>4</sup>

Many isostructural analogues have been synthesized.<sup>5</sup> This family of compounds is therefore particularly good for investigating the relationship between crystal structure and optical properties. Several isomorphous substitutions have been made in the KTP structure to

determine the origin of its NLO properties. A few substitutions have maintained or improved the second-harmonic generation (SHG) response of KTP.<sup>6</sup> The main reason for this seems to be the deformation of the  $M'\text{O}_6$  octahedra: the more distorted these octahedra are, the higher the efficiency of SHG of the material.<sup>7,8</sup>

Niobium is known to substitute isomorphously for Ti in a number of mixed-titanate compounds such as  $\text{KTP:Nb}^6$  or  $\text{K}(\text{TiNb})\text{O}_5$ .<sup>9</sup> This last family of compounds, with a different structure from that of KTP, can be made nonstoichiometric with a chemical formula of the type  $\text{K}_{1-x}(\text{Ti}_{1-x}\text{Nb}_{1+x})\text{O}_5$ .<sup>10</sup> In both structures, the presence of Nb is compensated by vacancies in the K site. In the case of  $\text{Nb}^{5+}$ , many different types of charge compensators were reported with the KTP structure: first, on the octahedral site by  $\text{Ga}^{3+}$  with a partial charge compensation and  $\text{K}^+$  vacancies induced<sup>11</sup> and  $\text{Mg}^{2+}$  in  $\text{K}(\text{Ti}_{1-x}(\text{Mg}_{1/3}\text{Nb}_{2/3}))\text{O}_5$  without induction of  $\text{K}^+$  vacancies;<sup>12</sup> second, on the tetrahedral site, by  $\text{Si}^{4+}$  with the structure  $\text{K}_{1.16}(\text{Ti}_{0.37}\text{Nb}_{0.63})(\text{Si}_{0.63}\text{P}_{0.53})\text{O}_{5.48}$ .<sup>13</sup> Also,  $\text{Ti}^{4+}$  cations in  $\text{KTiOAsO}_4$  (KTA) crystals can be completely substituted with  $(\text{Nb}^{5+}-\text{M}^{3+})$ <sup>14</sup> cation pairs

(with M = Al, Cr, Ga, Fe, In) on the octahedral site and it seems to be that  $Ti^{4+}$  can be completely substituted by  $Nb^{5+}$  when  $Ge^{4+}$  substituted As in the tetrahedral site in KTA crystals.<sup>14</sup> It was demonstrated that the KTA matrix was more stable for this substitution than the KTP matrix because the corresponding  $K(Nb^{5+}, M^{3+})-OPO_4$  phase was not observed. Cheng et al.<sup>15</sup> reported that substituting the  $Ti^{4+}-K^+$  pair with  $Nb^{5+}$  in the KTP crystal increases the optical birefringence and makes the material suitable for the SHG of blue light. Wei et al.<sup>16</sup> reported noncritical phase matching from YAG:Nd 1.06- $\mu$ m laser in 4.0% KTP:Nb crystal and obtained 4% efficiency in their first experiment. Our study deals with the preparation of solid solution crystals of the  $RbTiOPO_4$  family, obtained from the substitution of  $Ti^{4+}$  with  $(Nb^{5+}-Ln^{3+})$ .

Doping these crystals with lanthanide ( $Ln^{3+}$ ) ions is interesting because the ion photoluminescence and the NLO properties of the matrix can be merged to achieve self-induced effects. In previous studies,<sup>17-19</sup> we showed that when we used RTP crystals doped with Nb as a matrix to host  $Ln^{3+}$ , an  $Er^{3+}$  concentration similar to that obtained in other laser matrixes was achieved.  $Er^{3+}$  is interesting because of its emission around 1.5  $\mu$ m.<sup>20</sup> This ion is used in optical communications at long distances because of its efficient emission near the region of losses in silica fibers.<sup>21</sup> It is also used in medicine because of its emission at around 2.8  $\mu$ m.<sup>22</sup>

In this study, we have refined the structure of two new crystals:  $Rb_{0.855}Ti_{0.955}Nb_{0.045}OPO_4$  and  $RbTi_{0.927}Nb_{0.056}Er_{0.017}OPO_4$ . We paid particular attention to the positions occupied by dopant cations Nb and Er in the structure and measured the SHG efficiency in both materials. Finally, we compared our results with those of other members of this family and their respective NLO properties.

## Experimental Procedures

**Crystal Growth.**  $RbTiOPO_4$  doped with Nb (RTP:Nb) and co-doped with Nb and Er (RTP:(Nb,Er)) were obtained from solutions of molar composition  $Rb_2O-P_2O_5-TiO_2-Nb_2O_5-Er_2O_3 = 42.9-35.1-19.8-2.2-0$  and  $42.0-28.0-27.6-1.5-0.9$ , respectively, by spontaneous nucleation on a Pt wire. The experiments were carried out in a vertical tubular furnace controlled by a Eurotherm 818P controller/programmer using 25-cm<sup>3</sup> platinum crucibles filled with about 15 g of solution.  $Rb_2CO_3$ ,  $NH_4H_2PO_4$ ,  $TiO_2$ ,  $Nb_2O_5$ , and  $Er_2O_3$  (p.a.) were used as initial reagents, mixed in the desired ratios, and heated until bubbling of  $NH_3$ ,  $H_2O$ , and  $CO_2$  was complete. The solution was homogenized by maintaining the temperature at

about 50–100 K above the expected saturation temperature for 3–5 h, 1190 and 1180 K being the saturation temperatures of RTP:Nb and RTP:(Nb,Er) crystals, respectively. The difference in temperature between the surface of the solution and the bottom of the crucible was about 15 K. The temperature of the homogeneous solution was lowered in 10 K steps every 30 min, until crystals appeared on the platinum wire immersed in the solution. Then, we replaced the platinum wire with a platinum disk in contact with the surface of the solution to obtain larger crystals. After that, the temperature was decreased 20 K at a rate of 2.5 K/h to obtain the crystals with good enough quality and quantity for the latter characterizations. The quality of the crystallized phases was first checked by laboratory X-ray powder diffraction using a Siemens D5000 powder diffractometer.

**Dopant Concentration Analyses.** The crystals obtained were cleaned and analyzed by electron probe microanalysis (EPMA) to determine the concentration of the doping elements. A CAMECA SX-50 operating in wavelength dispersive mode was used. The samples were included in a polyester orthoaltalic-type resin and the surfaces of the samples were polished using diamond powders until a grain size of 1  $\mu$ m was reached. The concentrations of Rb, Ti, P, Nb, and O were analyzed at an electron current of 30 nA and the concentration of Er was analyzed at 100 nA. In all cases, the accelerating voltage was maintained at 25 kV. The raw intensities were corrected for dead time, background, and matrix effects using the PAP correction procedure.<sup>23</sup> The error in the determination of the content of Rb, Ti, and P in the samples in weight percent were around 1%, for Nb and O were around 3%, and for Er was around 15%. The cation concentrations from these analyses were taken as the nominal compositions in the two types of crystals of this work.

**Single-Crystal X-ray Diffraction.** A small piece of an as-grown crystal of RTP:Nb was selected (to avoid defects that are easily introduced in the material by cutting and polishing) to determine its single-crystal X-ray structure (XRD). Single-crystal XRD measurements were carried out at RT, and the structure was resolved by Patterson synthesis. Details of crystal data, data collection, and refinement are given in Table 1.

**Neutron Powder Diffraction.** Neutron powder diffraction (NPD) measurements on RTP:(Nb,Er) were taken with the D2B high-resolution diffractometer at the Institut Laue Langevin (Grenoble, France). This diffractometer is equipped with a bank of 64 detectors separated by 2.5° 2 $\theta$ , spanning an angular range of 160°. A good quality pattern was obtained at room temperature (RT) in the high-flux mode of D2B (see Figure 1). The wavelength used was 1.594 Å and the counting time was run about 3 h to have the desired statistics over the angular range 0–160° 2 $\theta$ . NPD data were analyzed by the Rietveld method, using the refinement program FULLPROF.<sup>24</sup>

**Second-Harmonic Generation.** The SHG properties of these crystals were studied by a powder technique.<sup>25</sup> The samples, powdered and graded between 5 and 20  $\mu$ m by standard sieves, were loaded into a 2-mm-thick quartz cell using a vibrator to ensure uniform packing. The powder was illuminated with a YAG:Nd pulsed laser. We estimated the fundamental power by measuring the 1064-nm energy reflected by the sample. The back-scattered harmonic power generated by the sample was collected using a lens and focused on a Si detector. We analyzed intersignals using a digital oscilloscope and used the ratio between the two maxima to describe the SHG efficiency process. This ratio was averaged over 100 laser shots. With this method we cannot measure the absolute efficiency of the SHG of the samples, so we compared this ratio with that of pure KTP, whose SHG efficiency is well-established in the literature.<sup>26</sup>

**Structural Characterization.** The crystals obtained had the characteristic shape of RTP crystals. There was only one difference: doping with niobium flattened them somewhat, as we explained in detail in a previous study.<sup>17</sup> The as-grown crystals were light gray-blue, but this color disappeared after an additional 3 h of annealing of the crystal in air at 773 K. In crystals containing Er, the characteristic pale pink color of this ion remained, while RTP:Nb crystals were colorless or pale yellow. The samples were free of impurities and the structural refinements of single-crystal XRD and NPD data were performed in the orthorhombic  $Pna2_1$  space group.

$\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}\text{OPO}_4$  Structure. We solved the structure of  $\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}\text{OPO}_4$ . The unit cell parameters were  $a = 12.947(3) \text{ \AA}$ ,  $b = 6.498(3) \text{ \AA}$ , and  $c = 10.579(7) \text{ \AA}$  and  $Z = 8$ . Parameter  $a$  was shorter,  $b$  was slightly longer, and  $c$  was clearly longer than the corresponding ones in the RTP structure. Details of crystal data, refinement, and atomic coordinates are given in Tables 1 and 2.

213

The main characteristic of this structure is that we obtained the enantiomorphic image of pure RTP. This means that while the  $x$  and  $y$  coordinates for all the atoms did not change very much, the  $z$  coordinates shifted considerably and were related to the  $z$  coordinate of pure RTP structure with a mirror plan at a height of practically a quarter in the  $c$  direction. This feature was also observed in the KTP:Nb structure when it was compared to that of pure KTP.<sup>6,27</sup>

214

215

216

Table 3 shows the occupation factors of the  $\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}\text{OPO}_4$  structure. The occupancies of the crystallographically independent positions for rubidium

cations were 0.832(5) for Rb(1) and 0.878(5) for Rb(2). 217

This follows the same trend as in the KTP:Nb samples.<sup>27</sup> 218

The occupancies of Ti sites were 0.910(8) and 0.090(8) 219

for Ti and Nb, respectively, in Ti(1) positions and 1.000- 220

(8) and 0.000(8) for the same cations in Ti(2) positions. 221

We refined the Ti occupancies by assuming that each 222

of these positions were fully occupied by titanium and 223

niobium atoms. There is a tendency for Nb to occupy 224

only the Ti(1) position. 225

The anisotropic displacements parameters of the 226

atoms are given in Table 4. 227

$\text{RbTi}_{0.927}\text{Nb}_{0.056}\text{Er}_{0.017}\text{OPO}_4$  Structure. We used the 228

structure of  $\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}\text{OPO}_4$  as a starting model 229

to refine the structure of the  $\text{RbTi}_{0.927}\text{Nb}_{0.056}\text{Er}_{0.017}\text{OPO}_4$  230

crystal by NPD. By carefully analyzing high-resolution 231

NPD data, we were able to study fine structural details 232

such as oxygen positions and, in particular, to determine 233

the location of dopants. In the refinements we used a 234

pseudo-Voigt profile function corrected for asymmetry 235

and a six-parameter polynomial function to reproduce 236

the background. 237

Table 5 shows the RT cell parameters, refined atomic 238

coordinates, and isotropic temperature factors of  $\text{RbTi}_{0.927}$ - 239

$\text{Nb}_{0.056}\text{Er}_{0.017}\text{OPO}_4$  structure from NPD. It also shows 240

the final reliability factors. Figure 1 illustrates the 241

agreement between the observed and calculated NPD 242

profiles. The high-angle region of the refined NPD 243

pattern (see Figure 1b) illustrates the excellent agree- 244

ment between the observed and calculated NPD profiles 245

for the best fit, which provide the occupations shown in 246

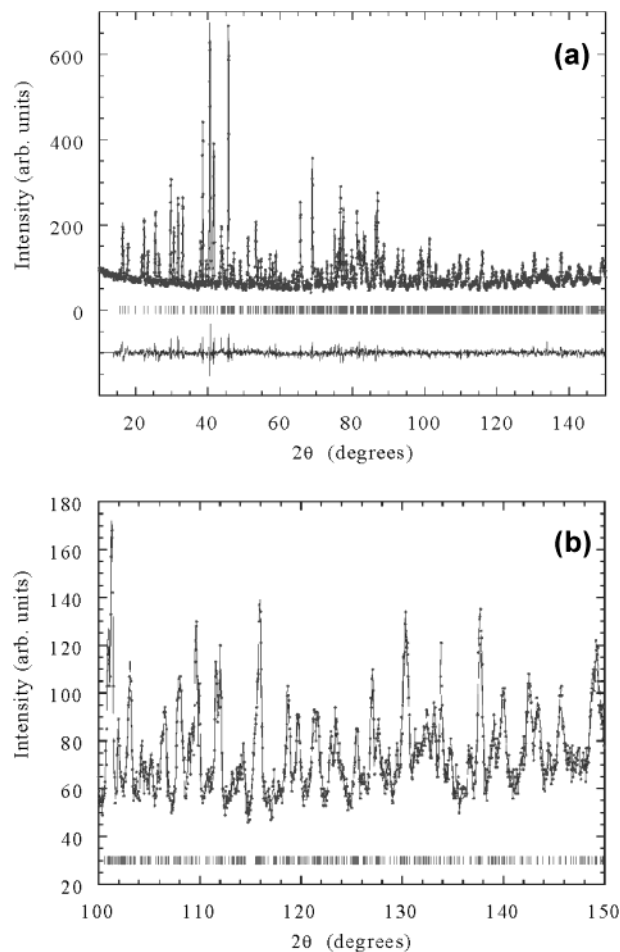

Table 3. 247

Reliability Factors  
 $\chi^2 = 1.65\%$ ,  $R_p = 5.39\%$ ,  $R_{wp} = 6.82\%$ ,  $R_f$  factor = 4.74%,  
 Bragg  $R$ -factor = 6.20%

248 The volume of the unit cell was larger because of the  
 249 increase in the atomic radii of  $\text{Er}^{3+}$ , but the distribution  
 250 of this larger volume was not the same for all three cell  
 251 parameters:  $a$  and  $b$  were 0.19 and 0.14% longer,  
 252 respectively, and  $c$  was 0.05% shorter than the param-

eters of the  $\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}\text{OPO}_4$  crystal. Our main  
 aim was to obtain reliable information about the dis-  
 tribution of the small concentration of Er and Nb cations  
 in the structure (we take advantage of the very different  
 Fermi lengths for neutrons of Ti (3.37 fm) and Nb (7.054  
 253  
 254  
 255  
 256  
 257

**Figure 2.** View of the structure of the RTP family of crystals illustrating the connected paths formed by alternating Ti(1)O<sub>6</sub> and Ti(2)O<sub>6</sub> octahedra. Projections parallel to (a) [010], (b) [100], and (c) [001] directions.

258 fm) or Er (8.03 fm). With this objective in mind, and  
 259 using a random distribution of Nb and Er among Ti sites  
 260 as a starting point, we performed different sets of  
 261 Rietveld refinements of the NPD data for different  
 262 models of the distribution of dopants. As expected, Nb  
 263 and Er only went to Ti sites in the RbTi<sub>0.927</sub>Nb<sub>0.056</sub>Er<sub>0.017</sub>-  
 264 OPO<sub>4</sub> structure. We also checked for the possibility of  
 265 vacant oxygen or rubidium. All the atomic positions,  
 266 including oxygen or rubidium sites, were fully occupied.  
 267 This was in contrast to some vacant rubidium sites  
 268 found in the RTP:Nb crystal. In our RbTi<sub>0.927</sub>Nb<sub>0.056</sub>-

Er<sub>0.017</sub>OPO<sub>4</sub> crystal, within a resolution of ~1%, we  
 269 found that the two Rb sites were fully occupied. 270

271 When we impose that Er and Nb cations randomly  
 272 substituted the two Ti sites, the reliability factors were  
 273  $R_{wp} = 6.88\%$ ,  $R_t = 4.79\%$ , and  $R_{bragg} = 6.29\%$ . However,  
 274 when we allowed for an inhomogeneous distribution of  
 275 the dopants, the reliability factors clearly improved. 276  
 277 When we fitted the occupation factors, the refinements  
 278 always converged to the same scenario: Nb atoms are  
 279 only substituted Ti(1) atoms at the center of the Ti(1)-  
 O<sub>6</sub> octahedra. On the other hand, Nb cations did not

substitute Ti atoms of the Ti(2)O<sub>6</sub> octahedra. We were able to refine the occupation factors of Nb and Er freely, with the only constraints that the Ti octahedra were fully occupied and had no vacant sites and that the concentrations of these cations in the structure were those given by EPMA analyses. The occupation factors therefore converged to the values given in Table 3: in our RbTiOPO<sub>4</sub> sample (doped with 5.6% Nb and 1.7% Er), Nb cations exclusively substituted Ti(1) sites. For Er, the refinements converged to the occupations 0.014(6) for Er(1) and 0.020(6) for Er(2). According to the errors, this is undistinguishable from or equivalent to Er being equally distributed between Ti(1) and Ti(2) (a fraction of 0.017 in each octahedra). However, the limit of the sensitivity of the technique is the highest for the

small concentration of Er, and the corresponding relative errors are very important.

**Second-Harmonic Generation.** SHG relative efficiency is defined as the ratio between  $\eta_{\text{sample}}$  and  $\eta_{\text{KTP}}$ , where  $\eta$  is the ratio between the powers measured at 532 and 1064 nm. In the studies of Rb<sub>0.855</sub>Ti<sub>0.955</sub>Nb<sub>0.045</sub>OPO<sub>4</sub> and RbTi<sub>0.927</sub>Nb<sub>0.056</sub>Er<sub>0.017</sub>OPO<sub>4</sub>, this was 1.2 and 0.7, respectively. These results are referred to KTP, now that the parameters of KTP are well-established in the literature.<sup>26</sup>

The SHG relative efficiency of Rb<sub>0.855</sub>Ti<sub>0.955</sub>Nb<sub>0.045</sub>OPO<sub>4</sub> was around 20% higher than that of KTP. As we showed in a previous study,<sup>17</sup> the SHG relative efficiency of RTP doped with Nb increases as the concentration of Nb increases until it reaches a maximum for a Nb concentration of around 4–5 at. % in the crystal. For higher concentrations of Nb, the SHG relative efficiency decreases. Our results therefore entirely agree with those of our previous studies of SHG relative efficiency in RTP:Nb crystals. Finally, the SHG relative efficiency of the sample containing Nb and Er was lower (0.7). If we compare this result with the expected one from a sample of RTP doped only with Nb and containing a similar concentration of this ion,<sup>17</sup> we can see that the SHG relative efficiency is clearly lower. This may be due to the presence of Er in the sample because this ion has a significant absorption of light from <sup>4</sup>I<sub>15/2</sub> to <sup>2</sup>H<sub>15/2</sub> manifolds in the green region.<sup>17–19</sup> We found, however, that this absorption did not dramatically decrease SHG relative efficiency, so we can conclude that the NLO properties of this crystal are as good as those of the RTP crystal.

## Discussion

Figure 2 shows the structure of this family of compounds. It is a network of chains of very distorted TiO<sub>6</sub> octahedra linked by PO<sub>4</sub> octahedra with periodic bond chains of  $-\text{PO}_4-\text{TiO}_6-$  in the *a* direction and along the *a*–*c* diagonal (Figure 2a). Ti(1) and Ti(2) octahedra alternate along the *c* direction to form helicoidal chains of linked TiO<sub>6</sub> octahedra (Figure 2a,b). Each Ti(1)O<sub>6</sub> octahedron shares two corners with Ti(2)O<sub>6</sub> octahedra through the OT(1) and OT(2) oxygens and the other four corners with PO<sub>4</sub> tetrahedra. If we take the plane containing the central Ti atom and the two OT oxygens as the equatorial plane of the Ti octahedra, then the equatorial plane of Ti(1)O<sub>6</sub> is almost parallel to the (010) plane, the *c* axis is almost parallel to the OT(1)<sup>iii</sup>–OT(2)<sup>ii</sup> (see Table 6) vector, and the *a* axis is approximately parallel to the OT(1)<sup>iii</sup>–O(1) vector. The O(5)<sup>ii</sup> and O(6)<sup>iii</sup> atoms are out of the plane and bonded to Ti(1) along a line almost parallel to the *b* axis. In the Ti(2) octahedron, the equatorial plane is almost parallel to the (100) plane and formed by O(7), O(8), OT(1), and OT(2) atoms. The *c* axis is approximately parallel to the O(8)–OT(1)<sup>iii</sup> vector and the apical O(3) and O(4)<sup>iv</sup> atoms are bonded to Ti(2) along a line almost parallel to the *a* axis. The typical long and short Ti–O bonds in the structure of KTP isomorphs are maintained, but if we compare their distances with those of pure RTP crystals, the Ti(1)–OT(1) and Ti(2)–OT(2) distances are shorter in these new crystals, while the Ti(1)–OT(2) and Ti(2)–OT(1) distances are longer (see Table 6 and ref 3). The PO<sub>4</sub> tetrahedra are not very different from those of the

558 undoped RTP compounds. The  $\text{RbO}_9$  cages occupy the  
559 channels left by the network of the  $\text{TiO}_6$  octahedra and  
560  $\text{PO}_4$  tetrahedra along the  $c$  direction (see Figure 2c).

561 It is of interest to note that in this family of crystals  
562 the  $\text{Ti}(1)\text{O}_6$  octahedra are larger than the  $\text{Ti}(2)\text{O}_6$   
563 octahedra. Another feature of the selective distribution  
564 of Nb is that only the former is occupied: the ionic  
565 radius of  $\text{Nb}^{5+}$  is slightly larger than the radius of  $\text{Ti}^{4+}$   
566 (0.64 and 0.605 Å, respectively<sup>28</sup>). Taking into account  
567 the much larger radius of  $\text{Er}^{3+}$  ions (0.881 Å<sup>28</sup>), the  
568 average Ti–O bond lengths in Table 6 for  $\text{RbTi}_{0.927}$ -  
569  $\text{Nb}_{0.056}\text{Er}_{0.017}\text{OPO}_4$  appear to suggest that Er has a  
570 preference for Ti(1) sites over Ti(2) sites. However,  
571 because of the importance of the errors associated to  
572 the Ti–O bond lengths in this powder sample, we cannot  
573 draw any conclusions from the differences observed.

574 Now we turn to the Rb vacant sites in the RTP:Nb  
575 crystal. Although EPMA measurements did not estab-  
576 lish the stabilization of vacancies of Rb in both types of  
577 crystals, the refinement of the structures gives a clear  
578 loss of Rb in the crystals that contained only Nb. This  
579 is an interesting aspect of doping RTP with Nb: the  
580 ability of the material to self-compensate electrically for  
581 the pentavalent substitution through the loss of Rb  
582 atoms. The mean Rb–O bond length was greater in the  
583  $\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}\text{OPO}_4$  structure than in the pure  
584 RTP.<sup>4</sup> This is consistent with the expansion of the cages  
585 in the structure caused by the loss of Rb atoms. In  
586 particular, the average Rb(1)–O distance (3.000 Å) in  
587 the  $\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}\text{OPO}_4$  crystal (which has Rb  
588 vacant sites) was slightly higher than that in the  
589  $\text{RbTi}_{0.927}\text{Nb}_{0.056}\text{Er}_{0.017}\text{OPO}_4$  and RTP crystals (2.99 and  
590 2.994 Å, respectively). This was not observed in the Rb-  
591 (2) $\text{O}_9$  cage, which had the same average Rb(2)–O bond  
592 length in all three materials: 2.993 Å (with Rb vacant  
593 sites), 2.99 Å (Nb, Er), and 2.992 Å (RTP). This indicates  
594 that when doping with pentavalent  $\text{Nb}^{5+}$  ions, Rb vacant  
595 sites are created mainly at the Rb(1) site. This inter-  
596 pretation also agrees with the different occupations of  
597 the Rb(1) and Rb(2) sites refined in  $\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}$ -  
598  $\text{OPO}_4$  (see Table 3).

599 Although Nb enters preferentially at the Ti(1) site in  
600 both crystal structures, the Ti(1) and Ti(2) sites are very  
601 similar crystallographically. If we define the distortion  
602 parameter  $\Delta_d = (1/6)\sum_{i=1-6}\{[d(\text{Ti}-\text{O})_i - \langle d(\text{Ti}-\text{O}) \rangle] /$   
603  $\langle d(\text{Ti}-\text{O}) \rangle\}^2$ , we can compare the distortion of the  $\text{TiO}_6$   
604 octahedra for our two crystals with that of other  
605 compounds of the KTP family (see Table 7). In all cases,  
606 doped and undoped, Ti(1) octahedra were more distorted  
607 than Ti(2) octahedra. Moreover, in the present concen-  
608 tration range, the distortion in the Ti(2) $\text{O}_6$  octahedra  
609 of RTP was not modified by doping with Nb or co-doping  
610 with Nb and Er. In our opinion the preference for  $\text{Nb}^{5+}$   
611 ions to occupy Ti(1) sites has an electrostatic origin

rather than a steric one. If we compare the Ti–Rb bond  
distances in the  $\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}\text{OPO}_4$  and  $\text{RbTi}_{0.927}$ -  
 $\text{Nb}_{0.056}\text{Er}_{0.017}\text{OPO}_4$  structures, we can see that these  
distances are quite shorter for the Ti(2) cation than for  
the Ti(1) cation (see Table 6). This implies that the  
electronic repulsion in the Ti(2) position is higher than  
that in the Ti(1) position. Consequently,  $\text{Nb}^{5+}$  tends to  
occupy Ti(1) positions to avoid this electrostatic repul-  
sion, an interpretation that is reinforced by the very  
similar radius of the  $\text{Ti}^{4+}$  and  $\text{Nb}^{5+}$  ions, while in the  
case of  $\text{Er}^{3+}$ , because of its lower electrical charge, this  
effect has not been observed.

It is believed that the markedly short Ti(1)–OT(2) and  
Ti(2)–OT(1) bonds are partially responsible for the  
optical nonlinearity in this family of compounds.<sup>29</sup>  
Phillips et al.<sup>30</sup> showed that the lengthening of the Ti-  
(1)–OT(2) bond to the same distance as the Ti(1)–OT-  
(1) bond was associated with a dramatic loss in SHG.  
Another example is  $\text{KSnOPO}_4$  (KSnP), where Ti is  
substituted by Sn. In this case the  $\text{SnO}_6$  octahedra are  
practically undistorted and, interestingly, the SHG  
efficiency drops by a factor of 70%. Although KSnP is  
isostructural with KTP, its structure is much closer to  
that of the centrosymmetric phase  $Pnan$ .<sup>31</sup> In our case,  
by looking at the Ti–OT bonds in  $\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}$ -  
 $\text{OPO}_4$  and  $\text{RbTi}_{0.927}\text{Nb}_{0.056}\text{Er}_{0.017}\text{OPO}_4$ , we did not find  
a clear or direct relationship between the difference in  
these bonds and SHG efficiency (see Table 7). We are  
therefore led to conclude that other factors also have a  
great influence on nonlinearity (such as modifications  
in the electronic structure due to doping). Notice, finally,  
that chemical bond calculations made by Xue and  
Zhang<sup>32–34</sup> for the KTP structure suggest that the K(2)-  
 $\text{O}_9$  and P(2) $\text{O}_4$  groups are also responsible for the  
nonlinear optical properties of this compound.

## Conclusions

We have solved the structures of  $\text{Rb}_{0.855}\text{Ti}_{0.955}\text{Nb}_{0.045}$ -  
 $\text{OPO}_4$  and  $\text{RbTi}_{0.927}\text{Nb}_{0.056}\text{Er}_{0.017}\text{OPO}_4$ , two new isos-  
structural of  $\text{KTiOPO}_4$ , and measured their SHG re-  
sponse. The main characteristic of these structures is  
that we obtained the enantiomorphic image of pure  
RTP. In both structures, the Nb and Er cations only  
went to Ti sites, and the refinements of the structures  
confirmed that in both materials Nb cations exclusively  
substituted Ti(1) sites. On the other hand, the situation  
for Er was undistinguishable, as it was equally distrib-

458 uted between Ti(1) and Ti(2) sites. We believe that this  
459 preference for Nb ions to occupy Ti(1) sites has an  
460 electrostatic origin rather than a steric one. Another  
461 remarkable feature was the ability of the material to  
462 self-compensate electrically for the pentavalent substi-  
463 tution through the loss of Rb atoms in the crystal that  
464 contained only Nb, but when Er<sup>3+</sup> was also present, this  
465 charge self-compensation was not necessary.

466 Measurements of SHG relative efficiency show that  
467 both these crystals are excellent nonlinear optical  
468 materials. In RbTi<sub>0.927</sub>Nb<sub>0.056</sub>Er<sub>0.017</sub>OPO<sub>4</sub>, we observed  
469 the absorption of green light by Er, but this did not  
470 decrease SHG efficiency dramatically. Comparison of  
471 the nonlinear optical properties of these crystals with  
472 those of other members of the structural family shows

473 that there is no clear or direct relationship between the  
474 difference in Ti–OT bonds, or the distortion of the TiO<sub>6</sub>  
475 octahedra, and SHG efficiency. Other factors also have  
476 a strong influence on nonlinearity.
